VOLUME XV.

No. 370.—January 4, 1867.

WATER-SUPPLY OF TOWNS.

OUR readers will be interested in learning that the Queen has appointed the Duke of Richmond, Sir John Thwaites, Colonel Harness, Alderman Phillips, Thomas Elliot Harrison, Esq., and Joseph Prestwich, Esq., to be Commissioners for the purpose of ascertaining what supply of unpolluted and wholesome water can be obtained by collecting and storing water in the high grounds of England and Wales, either by the aid of natural lakes or by artificial reservoirs, at a sufficient elevation for the supply of the large towns; and to report—firstly, which of such sources are best suited for the supply of the metropolis and its suburbs; and, secondly, how the supply from the remaining sources may be most beneficially distributed among the principal towns.

After the elaborate investigation which took place in reference to this subject in 1851, resulting in a voluminous report, *et præterea nihil*, we confess we have not much faith in Commissions. Their recommendation may be excellent, but, like most good advice, it is seldom listened to. It is, however, to be hoped that public opinion is now sufficiently alive to the paramount importance of pure water to enforce the serious consideration of whatever improvements in our water supply the above Commission will be led to recommend.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On the Effect of Ammoniated Solution of Copper upon Vegetable Fibre, by WILLIAM SKEY, *Analyst to the Geological Survey, New Zealand.*

WHEN cotton in either the raw or the manufactured state is placed in contact with a strong solution of ammoniated copper, a notable portion is dissolved, and by boiling the solution, by exposing it to the air for a short time, or by the addition of an excess of acid thereto, a flaky gelatinous precipitate falls, which when dried acquires all the physical characters of air-dried hydrate of alumina. It is insoluble in water, alcohol, ether, nitric acid, or potash, and it easily burns, leaving but a small quantity of ash.

But the effect of ammoniated solution of copper upon vegetable fibre when wrought up into filter-paper is still greater—the fibres of the paper are seen to swell very considerably, and ultimately the whole of the paper is dissolved to a viscid adhesive mass of the consistence of treacle, completely soluble in cold water, but rendered quite insoluble in water by boiling it therein, by exposing it to the air, or by addition of acid as before.

The greater susceptibility of filter-paper to the action of ammoniated copper can no doubt be referred to the chemical changes certain to have been effected upon the fibre of the paper by the many processes to which it has been subjected.

What is the composition of the substance produced from fibre by this cuprous solution has not been ascertained; but from its characters here described it bears considerable resemblance to gum, especially to that variety named inulin.

On the Constancy of Composition of Compounds usually considered Stable, by Professor* J. S. STAS.

COMPOUNDS which have generally been considered stable have been lately found to be essentially unstable. M. Marignac proved in 1853 that the composition of normal sulphuric acid is only definite within a certain limit. Dr. Roscoe has since found that the composition of a great number of aqueous acids is a function of the pressure which the vapour of these acids supports when they are submitted to distillation. For my part, I have proved that chloride of ammonium, according to the circumstances in which it is produced, can condense either hydrochloric acid or ammonia, but I attributed this fact to a physical cause, and one consequently which is independent of the chemical action which determines the formation of chloride of ammonium. M. Marignac, starting from the fact he himself observed, suggests that the sulphide and nitrate of silver, of which I have given new syntheses, may contain the one an excess of sulphur and the other an excess of nitric acid. Sulphide and nitrate of silver, being essentially stable bodies, may be submitted to causes capable of eliminating the sulphur and the nitric acid that may have been accidentally retained in them. In examining the details contained in my work, insufficient as they may appear in the eyes of certain chemists, it may be readily seen that I have made every imaginable effort to get rid of this cause of error; and yet the results do not agree with the composition these bodies should have, according to the atomic weights of their elements deduced from the hypothesis of Prout. "It may be," says M. Marignac, "that the composition of these bodies is only definite within limits, or even that they do not contain their elements in the absolute ratios of their atomic weights." This doubt attacks both the usually admitted fact of the constancy of the composition

* Abstract from *Memoirs of the Royal Belgian Academy.*

of stable compounds, and the invariability of the ratios of the weights of the elements forming the combinations.

Although, among well-established facts, I have not been able to meet with a single one calculated to cause the adoption of the views of the celebrated Genevese chemist, yet I have considered myself bound, were it only out of deference to his opinion, to submit this question to a new examination.

Among the conditions which might conduce to render inconstant the composition of stable compounds, are found temperature and pressure.

When we examine the syntheses of chloride of silver, given in my work published in 1860, we see that this body, although it may have been produced in very different circumstances, presents a composition which I think should be considered as constant. I should not venture, in fact, to attribute the insignificant difference of the results to any other causes than to the inevitable error of observation. Yet, in some cases, the chloride of silver was produced at a red heat by the combustion of silver in chlorine, and, in other cases, at the ordinary temperature, by the precipitation, by means of hydrochloric acid, of silver dissolved in nitric acid. Here, then, the influence of heat seems to me to be absolutely nothing.

Can we attribute a disturbing action to the intervention of pressure? Known facts do not seem to me to justify this supposition either. In fact, in my syntheses of nitrate of silver, I have ascertained that this salt loses none of its weight when fused in a vacuum—in other words, that it is without appreciable tension.

Again, I think I have proved that nitrate of lead, a salt which is certainly at the extreme limit of bodies which can be considered stable, may be left in a vacuum for a whole day, at a temperature only differing by 55° from that at which it is decomposed at an ordinary pressure, without any sensible loss of weight.

In order to determine by new researches the question whether, in the formation of compound bodies, pressure and temperature have any influence upon the ratio observed between the elements which form them, I have renewed the determination of the mutual relation between silver and chloride of ammonium, which has already been the subject of such long investigations on my part. I have chosen this method for two reasons—first, because it allows of introducing as a condition of formation both temperature and pressure, and next because the operation may be executed with a precision bordering upon mathematical exactness.

The mutual relation between silver and chloride of ammonium deduced from experiment depends both upon the purity of the silver and upon the composition of the chloride of this metal and the chloride of ammonium, while the composition of the latter depends upon its purity. Now the determination may be made at the ordinary temperature or at 100°; we may therefore determine, with great exactness, if between these limits of temperature the composition of chloride of silver undergoes any change.

On the other hand, chloride of ammonium may be produced at the ordinary temperature or at a high temperature; in the latter case it may be volatilised at the ordinary pressure, or in a vacuum.

Lastly, the ammonia for the production of the chloride may be taken from different sources, which permits of our controlling the results by each other.

The researches I have already published have proved that 100,000 parts of silver equal on an average 49,594 parts of chloride of ammonium produced at the ordinary temperature or sublimed at the usual pressure by determining the proportional ratio at from 10° to 15° Centigrade. I have sought what would be the results by varying the conditions in the manner I have just shown. To this end I have produced chloride of ammonium by three different methods—viz., 1st. By the ammonia from commercial chloride of ammonium suitably purified; 2nd. By the ammonia from purified sulphate of ammonium; 3rd. By the ammonia produced from the reduction of nitrite of potassium.

I sought first if, under similar conditions, the results are identical for the different chlorides and the same as those that I formerly observed. In order to allow every one to judge of the care I have taken in making these new determinations, I will enter into all the necessary details both on the subject of the preparation of pure silver and the preparation of chloride of ammonium. I will first state the means I employed to procure pure silver, and the precautions I took to make certain of the degree of purity of this metal. However lengthy these details may be, I think it is necessary, since this same metal enters into the syntheses of bromide, iodide, and nitrate of silver, of which I shall have to give an account in the notices on these subjects.

On the Preparation of Lime Crucibles for great Heats, by David Forbes, *F.R.S., &c.*

As a means of preventing the introduction of carbon and silicon into metals and alloys during the process of fusion, Deville some years back recommended the employment of crucibles turned in the lathe out of solid blocks of caustic-lime. The results of experiments made with such crucibles were found to be extremely satisfactory, and metals fused therein, as iron, manganese, nickel, cobalt, &c., were obtained far purer and more malleable and ductile than when fused in the usual clay or brasque crucibles. Unless, however, the crucibles required were of very small size, it was found difficult to obtain blocks of lime for shaping them sufficiently large and free from flaws; and experiment showed a considerable loss, both by breakage when shaping them and by their cracking when in the furnace. In order to obviate this, trials were made with clay crucibles lined with lime, but ineffectually, as these crucibles invariably melted down before the requisite heat was arrived at—a result due to the action of the lime itself upon the clay outer crucible.

After a number of experiments the following arrangement was found fully to answer the purpose, being capable of standing the heat of melted wrought iron or cobalt without fusion or cracking, as well as of being made of any reasonable size:—

A clay crucible of somewhat larger capacity than the desired lime one is filled with common lamp-black, compressing the same by stamping it well down. The centre is then cut out with a knife until a mere shell or lining of lamp-black is left firmly adherent to the sides of the crucible, and about half an inch or less in thickness, according to the size of the crucible; this lining is now well rubbed down with a thick glass rod until its surface takes a fine glaze or polish, and the whole cavity is then filled up with finely-powdered caustic lime and pressed down as before, and a central cavity cut out as before; or the lime-powder may be at once rammed down round a central core of the dimensions of the intended lime crucible.

This lime lining is naturally rather soft before being placed in the furnace, but upon heating agglutinates,

and forms a strong and compact crucible, which is prevented acting upon the outer one by the interposed thin lamp-black layer, and at the end of the experiment generally turns out as solid and compact as those made in the lathe.

Experiments made with such crucibles, even up to dimensions containing several pounds of metal, have proved them extremely well suited for these operations, and doubtless similar crucibles could be made lined with magnesia or alumina as required. In some cases ordinary black-lead crucibles lined with powdered lime, magnesia, or alumina, might possibly be found to answer.

TECHNICAL CHEMISTRY.

New Facts concerning Amalgamation, by M.* J. Nickles.

The action which mercury exercises on metals is not so energetic as that of sodium amalgam. This difference may be proved in a very simple manner, and in such a way as to be easily laid hold of by any audience.

Let a sufficiently large square of glass be taken, upon which, side by side, two gold leaves are cemented. If a drop of common mercury is conveyed to one of these leaves, the drop will be seen to adhere to it, and become flat, without increasing perceptibly in extent. Let a precisely similar operation be performed with a drop of sodium amalgam, and the drop will be observed to extend with astonishing rapidity, eating away and whitening all around it. In less than a few seconds the mercury will thus have obtained a superficies which many hundred times exceeds the section of the original drop.

In acting thus on gold leaf, the mercury sometimes creates a gap by drawing away the gold which it has met with and amalgamated by the way; sometimes, on the contrary, the precious metal remains in its place while amalgamating, and the square seems to be silvered on the points where the stationary amalgamation has taken place.

The spreading of the mercury on the surface of the metallic leaf does not always happen concentrically. It may have taken place in one direction rather than another, whether on account of the cohesive solutions which occur, or because the surface of the molecules does not everywhere present an equal degree of purity, especially when the metallic leaf has been put on with a cement.

This action of sodic mercury takes place even against gravitation, for it is not necessary that the gold-leaf should affect a horizontal position in order to be whitened in every way; the phenomenon is produced even when this leaf is placed vertically, so that the mercury may be seen rising along the metallic surface whitening or eating it away, continuing at the same time its work in a downward direction. Amalgam of thallium acts in the same manner.

This curious experiment does not succeed so well with silver, or beaten copper leaves, either because they are not so thin as those of gold, or because the permeability for mercury is less great in silver and copper than in gold. This question, to which I formerly applied myself, becomes complicated, besides, from the physical state of the metal; a piece of copper of a certain thickness takes less time to be penetrated with mercury and become brittle than a copper-leaf which has been reduced by laminating to the condition of tinsel, evidently because in the former case the metal is far more porous than in the latter.

It does not follow that because iron and platinum are not wetted by mercury they are incapable of uniting with it. The amalgam of iron and that of platinum are known; only, to obtain them, it is necessary to have recourse either to the battery or to a more electro-positive metal. Thus, to amalgamate iron, the metallic sheet has only to be rubbed with a zinc or brass brush, dipped in acidulated water, and a drop of mercury added. Here amalgamation takes place, by virtue of a galvanic effect, produced by a metal which, like sodium or zinc, is more positive than iron; in every case it remains superficial, the mercury not penetrating into the metal serving as substratum. Then it is also understood that amalgam of sodium can mercurise iron and platinum. I have made some remarks on this point, the results of which are as follows:—Amalgam of sodium promptly attacks a leaf of platinum cemented on glass; wherever this amalgam has touched, a hole is made. It is the same with leaves of aluminium. The same amalgam wets and instantly mercurialises a platinum crucible; but the metallic sheet is not permeable by it, for after six months' contact it had retained all its flexibility, and had not become brittle, as with iron and other metals not permeable by mercury; amalgamation remained superficial.

Ribbon magnesium, such as is used for lighting, is little affected by mercury; it is, without doubt, a little wetted by it under the influence of acidulated water; but amalgam of sodium is without action on it. However, thallium is wetted by mercury, and becomes brittle under its influence, thus resembling other metals, such as zinc, tin, lead, copper, silver, gold, and their alloys.

Laminated magnesium and thallium were not known thirteen years ago, when the aforesaid researches were published; their behaviour with respect to mercury adds, then, one more proof to the correctness of the proposition made at that time—viz., that "the metals which are wetted by mercury are permeable to it, and those which are not wetted are not penetrated by it."

To this proposition we may add that "when metals, which are not wetted by mercury, have been amalgamated by an indirect method, the mercury remains on the surface, does not penetrate into the depth of the metal, and consequently does not render it brittle."

It would be curious to prove the behaviour of indium in this respect; I submit the question to anybody who is fortunate enough to be possessed of this rare metal.

* *Journal de Pharmacie et de Chimie*, vol. iv. p. 330.

Action of Chlorine on Amylene.—M. Bauer, in an article in *Zeitschr. Chem.* p. 380, stated that at 17° C. chlorine is absorbed by amylene without any sensible disengagement of hydrochloric acid; at the boiling point the disengagement takes place, and at the same time there are separated—1. Chlor-amylene, $C_{10}H_9Cl$, boiling from 90° to 95° C. 2. Chloride of amylene, $C_{10}H_{10}Cl_2$. 3. Chlorinetted chloride of amylene, $C_{10}H_9Cl_3$, crystallising in camphorated masses. 4. Bichlorinetted chloride of amylene, $C_{10}H_8Cl_4$; a heavy limpid liquid, boiling at 230° to 240° C.

Iodine in Mineral Phosphates.—In trying an experiment with about half a ton of German phosphate of lime and sulphuric acid, I was astonished to see a very considerable evolution of iodine fumes. Having some misgivings on account of the novelty of the phenomena (to me), I exposed a sheet of paper smeared over with starch to their influence: the test was undeniable. Is this fact known to iodine manufacturers?—Smatterer.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, December 20.

DUGALD CAMPBELL, *Esq., in the Chair.*

THE minutes of the previous meeting were confirmed, and the donations to the library announced. Dr. E. A. Cook and Mr. James Forrest were formally admitted Fellows of the Society, and the following gentlemen were duly elected —viz., John Broughton, B.Sc., Chemist to the Government Cinchona Plantation, Madras Presidency; Mr. Watson Smith, 26, Portland Crescent, Manchester; and Mr. Walter Noel Hartley, Pathological Laboratory, St. Thomas's Hospital, London. The candidates proposed, whose names were read for the first time, were James William Hudson, Ph.D., Principal of Trafford College, Manchester; Mr. Joseph Ince, 26, St. George's Place, Hyde Park Corner; Mr. George Ottley, 196, Walworth Road.

Mr. W. H. PERKIN read a paper "*On the Basicity of Tartaric Acid.*" From the previous results of Hugo Schiff, Fritzsche, and others, tartaric acid is assumed to be tetrabasic; but the author has arrived at a different conclusion —viz., that it has a *bibasic* character, being, however, tetratomic, founding his opinion upon the study of certain new derivatives obtained from tartaric ether by the action of the chlorides of benzoyl, acetyl, and of other acid radicals. Of the two pairs of hydrogen atoms in tartaric acid, one only is replaceable or "basic," whilst the remaining couple possess very different functions, or are such as have been designated "alcoholic hydrogen." Some idea may be formed of the main points of this elaborate investigation from a notice of the several instances of replacement successfully accomplished:—

Benzo-tartaric Ether.—Acting with chloride of benzoyl upon tartaric ether, the author succeeded only in replacing one atom of hydrogen by benzoyl. This product, treated with dilute alcoholic potash, gave a crystalline body—ethyl-benzo-tartaric acid—besides Dessaignes's benzo-tartaric acid.

Similar results were obtained with paratartaric ether and chloride of benzoyl. The action of chloride of succinyl upon tartaric ether furnished an oily body containing two equivalents of tartaric ether bound together by the replacement of H_2 by diatomic succinyl. It is appropriately named succino-tartaric ether.

Aceto-benzo-tartaric Ether.—It was found to be possible to replace the two atoms of hydrogen in tartaric ether, the one by benzoyl, and the other by acetyl, giving rise to this body.

Aceto-tartaric Ether was formed by the replacement of one of hydrogen; and

Diaceto-tartaric Ether by two of hydrogen in the original body by the action of appropriate amounts of the chloride of acetyl. This second substance underwent no further change when brought in contact with sodium, tending to show that all the replaceable hydrogen had already been substituted in this compound.

Some interesting theoretical considerations bearing upon the constitution of paratartaric acid were next mentioned; after which Mr. Perkin described the results he had obtained by acting upon chloride of acetyl with dry tartaric acid. In this reaction a splendid crystalline substance was formed, which corresponded to the diaceto-tartaric anhydride; and from dried paratartaric acid an identical product was more slowly obtained.

Diaceto-tartaric Acid was formed from the last-named product by the action of water. It is a powerful acid, of bibasic character, forming two classes of salts—acid and neutral—many of which have been examined and described. The author alludes to Rochleder's previous notice of this substance and some of its salts in 1859.

Sodio-tartaric Ether and the disodium compound were prepared by the action of the alkali-metal upon tartaric ether, and the first of these gave, on treatment with iodide of ethyl, an oil, probably ethyl-tartaric ether.

The views advanced by the author in explaining the constitution of some of his new derivatives, were briefly remarked upon by Dr. WILLIAMSON; and

The PRESIDENT moved a vote of thanks to Mr. Perkin for his interesting communication.

A paper, in continuation of a previous research, and entitled "*On the Absorption of Vapours by Charcoal,*" by JOHN HUNTER, M.A., was read by the SECRETARY. The author has determined the rate of absorption of various substances in the state of vapour by a known bulk of cocoa-nut charcoal. The results for different temperatures are indicated in a series of tables. The following bodies were operated upon:—Aniline, carbolic acid, hydride of benzoyl, butyric acid, butyric ether, oil of turpentine, valerianic acid, aldehyde, acetic ether, acetone, nitrous ether, hydrochloric ether, formic acid, amylene, and perchloride of carbon.

Mr. E. T. CHAPMAN then read a paper "*On Some Reactions of Hydriodic Acid.*" The author referred to a previous paper, in which he stated that nitrite of amyl is decomposed by hydriodic acid, yielding nitric oxide and iodide of amyl. He has determined the amount of nitric oxide liberated under these circumstances, and finds it considerably short of the theoretical quantity. In fact, owing to a secondary reaction, a portion of the nitric oxide is converted into ammonia. When the amount of nitrogen present in the form of ammonia is added to that in the nitric oxide, the two are found to be exactly equal to the total amount contained in the nitrite. He finds that he can convert nitric oxide into ammonia by the action of boiling hydriodic acid. He has also determined the amount of nitric oxide liberated by the action of sulphuric acid on nitrite of amyl, and proved that the whole of the nitrogen is in this case obtained in the form of nitric oxide. The nitrates of the alcohol radicals appear to be decomposed by hydriodic acid in the same manner as the nitrites, though not so readily; the products being the iodide of the alcohol radical, nitric oxide, ammonia, and water.

Mr. HERBERT MCLEOD exhibited and described a very ingenious and efficient apparatus intended to serve the purpose of a *continuous aspirator*. After describing the arrangements in common use, and the leading features of his own invention, the author stated that, with a uniform pressure of water, the instrument acted with the regularity of a water-clock. It would be impossible to convey a correct idea of the instrument without resorting to pictorial illustration.

The PRESIDENT then adjourned the meeting until Thursday, January 17.

ACADEMY OF SCIENCES.

December 10.

"*Reply to the Critical Observations of M. Spierer relative to the Parallax of the Depths of the Solar Spots,*" by M. Faye.

"*On Chirurgical Intoxication,*" by M. Maisonneuve.

"*On the Longitude of Rio de Janeiro,*" by M. Mouchez.

"*On Molecular Forces in Liquids in Movement, with their Application to Hydrodynamics,*" by M. Kleitz.

"*Application of the Diapason to Horology,*" by M. Maudet-Breguet.

"*On the Poisonous Principles in Cholera Dejections,*" by M. C. Thiersh.

"*Observations on Dialysis and Endosmose,*" by M. Dubrunfaut.

"*On the Reciprocal Actions of Hydrocarbons,*" by M. Berthelot. In continuation of his researches on the mutual action of hydrocarbons, the author has examined the action of ethylen on phenyl, chrysen, and anthracen, and the action of free hydrogen on chrysen, naphthalin, and

anthracen. A mixture of ethylen and phenyl passed simultaneously through a red-hot tube yields, on the one hand, benzol and styrol (displacement of benzol by ethylen)—

$$C_{12}H_4(C_{12}H_6) + C_4H_4 = C_{12}H_4(C_4H_4) + C_{12}H_6,$$

and also anthracen and hydrogen (displacement of hydrogen by acetylen)—

$$C_{12}H_4[C_{12}H_4(H_2)] + C_4H_2(H_2) = C_{12}H_4[C_{12}H_4(C_4H_2)] + 2H_2.$$

Ethylen and chrysen passed simultaneously through a hot tube produce principally anthracen and a little naphthalin by displacement of the benzol. Ethylen and anthracen form a large quantity of naphthalin. The reactions of hydrogen are less characteristic. Hydrogen and chrysen give rise to benzol and phenyl. Hydrogen and naphthalin scarcely react upon one another, and the action between hydrogen and anthracen is still more difficult, traces of benzol and acetylen being formed in each case. The author deduces from his researches the law that in these reactions there is a reciprocal change between the hydrogen, benzol, and ethylen, regulated by the relative masses of these three bodies. The study of reten has led the author to some new facts. He considers it to be a homologue of anthracen. The reaction of formen on benzol was not attended with success. It was only at the softening point of porcelain that the commencement of reciprocal action was observed, attended by the production of a minute quantity of anthracen and naphthalin.

"*On Some Properties of Chloride of Sulphur*," by M. Chevrier. The author has studied the action of phosphorus on chloride of sulphur, and has succeeded in converting it almost entirely into chlorosulphide of phosphorus. In a large globe of seven or eight litres' capacity, pour three equivalents of chloride of sulphur SCl, and heat to the boiling point. Then add in small fragments one equivalent of phosphorus. After each addition well agitate the vessel; the result will be a yellow liquid consisting almost exclusively of chlorosulphide of phosphorus, holding sulphur in solution. Distil, rejecting the small portion which comes over below 125° C., the boiling point of chlorosulphide of phosphorus. The reaction is—

$$P + 3SCl = PCl_3S + 2S.$$

The author has prepared half a litre of this body in one day. An attempt to prepare chlorosulphide of arsenic failed. Upon working in identically the same manner, only chloride of arsenic and sulphur were produced—

$$As + 3SCl = AsCl_3 + 3S.$$

The author has here observed a curious fact connected with the crystallisation of sulphur. Towards the end of this operation, the yellow liquid on cooling deposits long prismatic needles of sulphur, amongst which are easily distinguished octahedra of relatively considerable volume. The prismatic sulphur is opaque; the octahedra are, on the contrary, very brilliant. They appear to form only towards the end of the cooling. The experiment is very easy to repeat, and each time it gives the same mixed crystallisation. In 1848 M. Pasteur observed an analogous fact in the preparation of sulphide of carbon.

"*On the Direction of the Vibrations in Polarised Light*," by M. Mascart.

"*On the Analysis of the Soluble Principles of Vegetal Earth*," by M. Schlösing. The researches of Messrs. Huxtable, Thompson, Way, &c., have shown that soils have an absorptive power, ranging according to their nature, for alkalis, but that this power is *nil* for hydrochloric, nitric, and sulphuric acids. The author has confidence in this displacement method when acids are to be determined in the solution which nourishes vegetables; but as regards the alkalis, the method yields a minimum result only. Indeed, if equal weights of earth are soaked with solutions of alkaline salts identical in composition but unequal in volume, that portion of earth which is in the presence of the greatest volume will absorb the most alkali. Thus, when the author employs the method of displacement, he accumulates in the lower layers, solutions of alkaline salts. He, therefore, permits the earth to take up more alkali than it had before, and impoverishes his solutions. That does not prevent the establishment of a new equilibrium, whence results the constancy of composition of the first liquids collected. New researches are, therefore, necessary to determine the amount of this impoverishment, which evidently varies according to the nature of the soil.

"*Note on Crystallised Oxalate of Lime*," by M. Monier. The author has obtained crystallised oxalate of lime by carefully reversing a vessel containing a dilute solution of oxalic acid into a denser bath of sucrate of lime. Owing to the difference of density, the oxalic acid rests without mixing on the alkaline solution, and slowly combines to form a well-crystallised salt. Ammoniaco-magnesian phosphate may be obtained in a similar manner.

December 17, 1866.

"*On the Parallactic Inequality of the Solar Spots*," by M. Faye.

"*On the Periodical Variations of Temperature in February, May, August, and November*," by M. C. Sainte-Claire Deville.

"*On the Composition of the Stone Implements found in Celtic Monuments and amongst Savage Tribes*," by M. A. Damour.

"*New Theory of Crystalline Reflection, according to Fresnel's Ideas*," by M. A. Cornu.

"*On the Selenides from the Mines of Cacheuta*," by M. Domeyko. A deposit rich in selenides was discovered about six years ago, at Cacheuta, in the province of Mendosa, at the lower part of the Andes. The seleniferous minerals have as yet only been found in one vein, the direction of which is nearly north and south, and the angle of inclination 90°. It intersects the system of stratification at almost a right angle. The author has been led to the conclusion that there are three associated minerals mixed in different proportions—first, a selenide analogous to eukairite $(Ag,Cu)Se$; secondly, $(Fe,Co)Se$; and, thirdly, $PbSe$. The first two possibly form a polyselenide whose composition approaches the formula $(Fe,Co)Se + 2(Ag,Cu)Se$, and in which the selenide of silver and subselenide of copper, which are isomorphous, replace one another, as do the sulphide of silver and subsulphide of copper in the double sulphides of Chili. These selenides have great outward similarity; their hardness is 2·5, and their density from 6·3 to 7·2. They are very fusible, and before the blowpipe give the characteristic odour of selenium. In a closed tube, black and red selenium sublimes. In an open tube they give variable proportions of selenious acid mixed with a reddish sublimate. Nitric acid attacks and dissolves these minerals easily with liberation of selenium, which disappears on boiling. Pure and hot hydrochloric acid also attacks these selenides with evolution of part of the selenium as seleniuretted hydrogen. The best method of analysis was found to be separation of the selenium by means of dry chlorine, and the lead and silver by dissolving in nitric acid, and precipitation by hydrochloric and sulphuric acid. The percentage of selenium varied between 22·4 and 30·8 per cent.

"*On the Spontaneous Generation of Infusorial Animalcules*," by M. A. Donné.

"*Observations on the Previous Note*," by M. Pasteur.

"*On the Reciprocal Action of Hydrocarbons*," by M. Berthelot.

"*On the Seeds of Buckthorn, from a Chemical and Industrial Point of View*," by M. J. Lefort. This is a continuation of a paper which we noticed some weeks ago. The object of this new memoir has been to find out under what circumstances rhamnegine passes into rhamnine; to show

how each of these acts in the dyeing of tissues, and how these two colouring matters may be industrially utilised. The author finds that rhamnine, which is so easily separated from buckthorn, and which has not hitherto been used, will yield clearer yellows than will rhamnegine.

"*On a New Hydrocarbon*," by MM. C. Friedel and A. Ladenburg. Certain theoretical considerations, and the existence of a compound in which four hydrocarbon groups C_2H_5 are united by one atom of silicium, led the authors to seek for a hydrocarbon having an analogous constitution. After many fruitless efforts they succeeded, by acting on methylchloracetol with zinc ethyl, in preparing a hydrocarbon, C_7H_{16}, which they represent by the formula—

$$C\begin{cases}2CH_3\\2C_2H_5\end{cases}$$

The new body boils between 86° and 87° C. Its vapour density is 3·62, and its specific gravity at zero is 0·7111.

"*On Some New Derivatives of the Fatty Acids*," by M. H. Gal. The author has prepared monacetyle-glycolic ether; monacetyle-butyllactic ether; monobutyrile-butyllactic ether; and several other bodies.

NOTICES OF BOOKS.

Inorganic Chemistry. By the late George Wilson, M.D. Revised and enlarged by Stevenson Macadam, Ph.D. With New Notation added. W. and R. Chambers.

This is a new edition of a work published by the late Dr. Wilson sixteen years ago, which the rapid progress of the science has necessarily rendered obsolete. Large alterations and additions to it have been made by Dr. Macadam, with the view of bringing it up to the present state of the science, but we cannot congratulate him on the mode in which he has performed his task. In place of being a clear and concise, though very elementary, sketch of the state of the science, as the original work at the date of its publication certainly was, the present edition abounds in loose and inaccurate statements.

As an illustration, we may quote the well-known definition of atom and molecule, which is given in these words:—

"An *atom* of a substance is the smallest proportion which will combine with other particles of matter, but which cannot exist in a separate form. *Molecules* are the smallest portions of matter which can exist in a separate state. Thus, an *atom* of water is the least quantity which will combine with other substances; whilst the *molecule* of water is the smallest proportion which will exist by itself, and which might be obtained by the ultimate division of a portion of water."—Page 14.

In which passage the illustration is not only entirely erroneous, but renders the definition itself perfectly unintelligible.

In the chapter on the Laws of Combination by Volume, on which the whole system of modern chemistry is founded, numerous errors exist. We are told for example that—

"No elementary substance yields a greater volume than hydrogen, but the compound gases and vapours give one twice as great as that of this gas. They have, accordingly, placed after them a double square | | , which has twice the capacity of that of the simple or elementary substances."—Page 70.

From which we must infer that the editor is ignorant of the fact that the atoms of cadmium and mercury occupy twice the volume of an atom of hydrogen. We might have supposed this to be an omission; but in the table in the previous page, mercury is set down as occupying one volume, and among the experimental vapour densities that of mercury is given as 201·11, which is just double the number actually found.

The statement regarding the volume of compound gases is curiously inconsistent with the following passage which appears on the next page:—

"The vapours of organic substances afford examples of both classes. No organic substance yields a vapour less than that of hydrogen or one volume. The organic substances which play the part of simple bodies, and thus combine together, or with other substances, like elementary bodies, have a combining volume similar to that of hydrogen, namely, 1 or | | , and an example of this class is ordinary ether (!); whilst other organic substances, which conduct themselves like compounds, such as hydrochloric acid, have a double combining volume, namely, 2 or | | ; and an illustration of this group is the vapour of alcohol."—Page 71.

While, as if to make confusion worse confounded, on the page immediately following, ether is represented as occupying two volumes.

The descriptive part of the work is equally inaccurate; in proof of which we select the account of Nordhausen sulphuric acid:—

"Green vitrol consists of sulphuric acid, oxide of iron, and water, its exact composition being $FeSO_4+7H_2O$. It is first strongly dried, the effect of which is to expel the greater part of the water it contains. About a seventh part of that, however, is always, and purposely, retained. The dried sulphate of iron is then exposed to a red heat in stoneware retorts. Half of the sulphuric acid of the sulphate comes over in combination with water, whilst the other half is decomposed into sulphurous acid, which is evolved as gas, and oxygen, which converts the protoxide of iron into peroxide.

"Nordhausen acid varies in strength, but when strongest may be regarded as consisting of one combining proportion of water, and two of sulphuric acid, H_2O+2SO_3 [by old notation, $HO+2SO_3$]. It is twice as strong as the strongest English sulphuric acid, or oil of vitriol."—Page 161.

The merest tyro in chemistry must see that, if one-seventh of the water of the green vitriol is retained, no Nordhausen acid can be got, but that the product must be the glacial acid $H_2SO_4H_2O$.

Our readers will probably be interested to know, on the authority of Dr. Macadam, that there are three compounds of hydrogen and oxygen, one having the formula H_2O_3; that the air dissolved in water consists of two volumes of oxygen to one volume of nitrogen, and not of 1·87 of nitrogen to 1 of oxygen, as we had previously supposed; that olefiant gas is CH_2, and that this quantity occupies two volumes; that hypophosphorous acid is HPO, and not HPH_2O_2, and that the calcic hypophosphite is CaP_2O, which is not even consistent with the formula given for the acid; that nitrate of copper, according to the new notation, contains six molecules of water of crystallisation; and that, by calcination in a current of air, galena "is converted in part into sulphate of lead, $PbSO_4$, and by subsequent *increased heat the whole is reduced to the state of metal.*"

These are but a few examples of errors and inaccuracies which abound in almost every page of this work, and make it a most unsafe guide for the student.

At the present time, when the study of chemistry is being slowly introduced into elementary schools, it is especially necessary to keep a watchful eye on the character of the manuals likely to be used, for it is manifest that the success of the movement must greatly depend on their accuracy and precision. In these qualities the work before us is eminently deficient, and we have thought it necessary to point out its shortcomings very distinctly, because, from its being one of an "Educational Course" published by Messrs. Chambers, it is not unlikely to find its way into the hands of teachers whose knowledge of such subjects is necessarily often but little in advance of the text-books they use, and who may not be able to detect its errors.

CHOLERA AND ANTISEPTICS, 1866.

(A) *The Arrest and Prevention of Cholera; being a Guide to the Antiseptic Treatment.* By A. E. Sansom, M.B. Lond. London: Churchill.

(B) *Asiatic Cholera.* By F. A. Burrall, M.D. New York: Wm. Wood and Co. London: Stevens Bros., Covent Garden.

(C) *Reprint from the Appendix to the Third Report of the Cattle Plague Commission.* By Wm. Crookes, F.R.S. London: J. H. Dutton, 1, Wine Office Court, Fleet Street.

(D) *Tenth Annual Report of the Medical Officer of Health for the Holborn District Board of Works, London.*

(E) *Handbills relating to Precautions to be taken against the Cholera.* Various.

(*Continued from Vol. XIV., page 262.*)

It is generally stated that there is a diminution in the quantity of ozone during cholera epidemics, just as an excess is found in an epidemic of influenza. The latter fact seems to be better established than the former. Of other disinfectants recommended by medical officers and chemists we may notice the following:—

Heat.—Dr. Frankland denies that a boiling heat destroys the vitality of the cholera germ. This is not generally agreed with, and, if true, would upset the doctrine of the disease being due to organised particles, since nothing of the kind could long resist a heat of 212° F. An obvious fallacy is difficult to be guarded against, for if water be so treated, and the noxious germs destroyed, it is after such treatment still exposed to germs in the atmosphere. However this may be, boiling is almost universally recommended for the disinfection of water, and was so during the late epidemic almost without exception. The poison of scarlet fever (inferior to few in point of virulence) is well known to be destroyed at a temperature of 220° F. Speaking of disinfection generally, Dr. Tanner observes: "Woollens, bedding, or clothing may be thoroughly purified by exposing them for about two hours in an oven at a temperature of 220° F."

Solution of chloride of iron is named as one of the chief disinfectants, with chloride of lime, Burnett's fluid, and Condy's liquid, in the memorandum drawn up by the metropolitan medical officers of health. We presume that this is meant to replace the sulphate, as recommended by Pettenkofer, for the disinfection of drains. "Sulphate of iron or a solution of carbolic acid" is recommended for the district of St. Giles, Camberwell. Professor Roscoe and Dr. Noble recommend the following for the township of Manchester:—

"*As a disinfecting liquid,* a neutral solution of the chlorides of manganese and iron (the neutralised refuse liquor from the manufacture of chlorine), called in the report 'the disinfecting fluid.'

"*As a disinfecting powder,* chloride of lime or bleaching-powder, called in the report 'the disinfecting powder.'

"These substances are selected (1) because they are known to be efficacious; (2) because they can be obtained in the necessary large quantities at a moderate cost; and (3) because the mode of their employment is simple.

"Other substances may possibly act as effectively, but these are chosen as best suiting the present purpose.

"The 'fluid' is to be used chiefly for general disinfection, by the authorities, of the drains and sewers of the low-lying and suspected neighbourhoods. *One gallon of the 'fluid' will disinfect* 10,000 *gallons of ordinary sewage.*

"The 'fluid' is also to be used for special disinfection of the house drains, &c., when needed.

"The 'powder' is to be used for the special disinfection of linen, utensils, bedding, and dwelling-houses, as hereafter described. *One pound of this powder will disinfect* 10,000 *gallons of ordinary sewage.*"

From the following paragraph of this same handbill we should think that the sewage state of Manchester is by no means perfect.

"*Discharges from the Sick.*—Two tablespoonsful of the 'powder' to be at once distributed over the contents of the vessel, which must then be covered and at once emptied. These discharges, even after disinfection, must on no account be thrown out into *middens, privies, or sludgepools* in the neighbourhood of the dwelling-houses but got rid of through the *street drains,* which must be frequently disinfected and flushed as suggested. *Where there are water closets these would of course be used in preference to the street drains.*"

If sludgepools are the same as our cesspools, such a fact may account for the unhealthiness of Manchester in part, for in London there are *very few* cesspools now, while the drainage and sewage of Birmingham is still better. Thus, from the report on the "Health of London" for October 27, 1866, we find the rate of mortality for the week was

22	in	1000	for Birmingham,
24	"	"	London,
30	"	"	Manchester,
32	"	"	Liverpool;

and this relative order is tolerably constant.

Many salts that fix noxious gases we find not mentioned, such as the acetates of copper and lead. Theoretically, for the destruction, or rather fixation, of sulphuretted hydrogen, common Goulard water would have been thought to be most useful, but sulphate and chloride of iron seem to be generally preferred for the purpose. This probably acts by virtue of the persalt of iron present oxidising the sulphuretted hydrogen. Of gaseous disinfectants and antiseptics the lower oxides of nitrogen seem to have been replaced entirely by hypochlorites, and justly so, for the preparation of the latter is much more easy, and the gas also, or mixture of gases, evolved is less irritating.

Iodine also deserves a fair trial, since its properties of acting on morbid products are well known to be very different from those of chlorine, and such properties may also be of use quite apart from mere disinfection. Dr. Tanner gives the following note of its use:—"This agent has been recommended for disinfection and deodorising purposes by Wynn Williams, Campbell De Morgan, Nunn, and Richardson. 200 grains are placed in a common chip box and suspended over the patient's bed. . . . If desired, it may be at once sublimed and the vapour diffused by placing it on a heated fire-shovel. In rooms occupied by *small-pox patients, the air may be kept free from smell* by using iodine in this manner—probably the *strongest proof* which could be adduced of the value of this simple and manageable remedy." We must demur to the statement that deodorising power is a strong proof of disinfection. The fumes of acetic acid are doubtless also soon to have another trial, when the present researches as regards its therapeutic value (for arrest of cancer-cell multiplication) are more matured.

In concluding the subject of disinfection, it may be well to draw notice to the esteem that chlorine was held in when it was the only agent of the kind known. Thus Abernethy says of disinfectants:—"They are sometimes useful, very useful indeed, for they make such an abominable stink that the patient is obliged to have the windows opened." It would be difficult now to find any Medical man who would deny the importance of disinfection.

Cholera and diarrhœa may be stated to be either epidemic or endemic. Cholera is perhaps endemic to a small extent in England, but the nature of this endemic cholera probably is essentially distinct from that of the epidemic type, for there is no evidence that endemic cholera becomes epidemic in England or temperate climates. As regards diarrhœa, Dr. Sansom draws the line sharply between the two parallel kinds of diarrhœa, and shows that rationally they require different treatment. We believe that the members of the

Cholera Congress came to the conclusion that cholera might be produced by the poison of choleraic diarrhœa. Probably the proximate or determining causes of endemic disease become the *predisposing causes* of epidemic disease.

In speaking of typhoid fever, Dr. S. Gibbon remarks—It is caused by the emanations from sewers and from heaps of decaying animal and vegetable refuse. . . . *It resembles* the cattle plague in its pathological character, but some physicians whose opinions are entitled to respect argue that sewers, drains, and dung-heaps do not *per se generate it*, but they must first receive the specific poison from the excrements of patients suffering from the disorder before they can distribute the poison to others. Whichever be the correct opinion, it can make but little difference as to the measures we ought to adopt to prevent it. We can reconcile the two views by looking upon the disease as endemic in the one case, epidemic in the other, the *same cause* being in the former case determining, in the latter predisposing. The successful treatment of the cattle plague has shown that it is not endemic, and the pathological resemblance of it to typhoid fever adds force to these remarks, since it cannot be so stamped out, being endemic. We have the best authorities in favour of sewage being a determining cause of typhoid; just as overcrowding is generally supposed to be the determining cause of typhus, but in some epidemics perhaps generated endemically (as in the case of fevers in temperate climates), so the causes before determining then act also as predisposing causes. If this be so, such causes become doubly dangerous at such times, and so the danger is more easily detected. Thus the cattle plague, without doubt, is not endemic in England, but it is both endemic and epidemic elsewhere, and the cause which predisposes in England may be determining elsewhere. In this respect cholera (Asiatic) resembles the cattle plague; the filth in India causes an epidemic which is predisposed to by filth in England. Dr. Jenner thus illustrates this shifting of cause from predisposing to determining or exciting:—A traveller fatigued and hungry crosses a marsh where miasmata abound. If he is attacked with ague at the beginning of the marsh, fatigue and hunger are the predisposing causes; if after crossing he becomes fatigued and hungry, these causes, before predisposing, become exciting. The constancy of action of such predisposing causes may be appreciated by the following:—"It is also an interesting feature connected with cholera that a second epidemic will sometimes commence in the same house where the first began, even in the same room. Thus in Toeplitz the cholera broke out in the same house near a canal two years in succession. In Edinburgh one of the first two cases, which occurred in 1848, was in the same house where the malady had first appeared in 1832; while in Leith in 1832 and 1848 the disease commenced in the same room. The epidemic in Rheims of 1849 and 1854 also originated in the same house."—Burrall.

The question that suggests itself is—Can we trace these predisposing causes often, and accurately define them? Not altogether; but we know that there are many predisposing causes to disease in general, and also many that predispose to a class of diseases specially.

Elements of Chemistry. Part III. Third Edition. By Wm. Allen Miller, M.D., V.P.R.S. London: Longman, Green, Reader, and Dyer. 1867.

In this edition of the well-known Elements, Dr. Miller follows the notation that he adopted in vol. ii. of the same edition, with the nomenclature of Berzelius. He observes that "the change in notation will doubtless be attended with more inconvenience, though it is certain to be adopted, since in none of the recent investigations made in this country, and in very few of those on the Continent, is the old method made use of." As regards the nomenclature of chemistry, which is at present open to serious charges of inconsistency, it certainly is better to speak of ferrous and ferric in the same sense that we speak of nitrous and nitric oxide. It is feared by the author that such change may appear pedantic and strange, in the face of such terms of modern chemists as stibiotetramethylium. The nomenclature of the alkaloids also requires some amendment; thus we have conylia and nicotylia side by side with sparteia, and cinchonia is isomeric, not with cinchonidia, but with cinchonidine. Of course these are only trifles, but it is highly desirable that one and the same body should not have three names, as conia, coniine, and conylia, especially when terms such as benzol (benzine), benzile, and benzoyl mean such very different things. A reform in this direction is highly desirable, and any simple plan of uniform nomenclature would soon be accepted by all.

The great advantage of this book over others of the same class is that all that concerns the manufacturer and physiologist is explained by chemical theories, and so the field of the chemist is extended as it should be, and made a centre among the allied sciences. Part I. treats of this connexion with the physical sciences; Part II. with geology and mineralogy; while in Part III. economic, physiological, and botanical questions are connected with chemistry. It is obviously a gain for all that an accurate science should connect together others much less so.

We have a good account of the nutrition of animals and vegetables; pus and excretions generally; the saliva, gastric fluid, &c.; muscular tissue; components of brain and nerves, hairs, feathers, sponge; preparation of the various leathers (morocco, wash, and glove); preparation of glue and size; preparation of snuff; manufacture of soap, wine, malt, &c. The book can therefore be recommended to a very large class of readers.

But while chemistry thus enlarges its borders, it should also secure its former possessions, and make them more compact. Thus many substances formerly organic are now undoubtedly inorganic. Hydrocyanic and formic acids can be made synthetically almost as easily as the complicated inorganic ones; and this process of transference from the one kingdom to the other, results in gain for both, since the unity of all chemistry is shown with the gradual transition that always exists in nature. This has been shown so clearly in some other English text-books (especially those of Williamson and Odling) that the success of this scheme of arrangement of general matter requires general recognition. Another matter in the order of treatment of subjects is highly advantageous to the reader—*i.e.*, the consideration of the constitution of sugars and fermentation before speaking of alcohol. This is not usual; but the error of talking about things before unmentioned is avoided. Of course by this method the other advantage is lost—*i.e.*, of discussing alkaloids and organic bases of doubtful theoretical constitution immediately after the sugars—the transition being followed through the glucosides from bodies of known to those of unknown atomicity. We would direct special attention to the subject of fermentation, which is very fully treated, and is of such great interest at present. Dr. Miller's book holds a position of its own in the English language, and it is very difficult indeed to say by what book we could replace the present edition. It will be a very capital Christmas present for all who take an interest in chemical science.

CONTEMPORARY SCIENTIFIC PRESS.

[Under this heading it is intended to give the titles of all the chemical papers which are published in the principal scientific periodicals of the Continent. Articles which are merely reprints or abstracts of papers already noticed will be omitted. Abstracts of the more important papers here announced will appear in future numbers of the Chemical News.]

CORRESPONDENCE.

Test for the Purity of Glue.

To the Editor of the Chemical News.

Sir,—As I am compelled in my business to use a considerable quantity of glue, and being at a loss for a good test to ascertain the comparative value of the various qualities submitted to me, I would feel obliged by your informing me of the best method for doing so. I am, &c.

J. S.

Glasgow.

Deflection of a Galvanometer by a Ray of Light.

To the Editor of the Chemical News.

Sir,—Your correspondent "Phototype" will find a short description of the experiment in which a galvanometer needle is deflected by a ray of light falling on a silver plate, at page 153 of "Grove's Correlation of Physical Forces," fourth edition. I am, &c.

J. Noble.

Woolwich, December 13, 1866.

Mercuric Oxalate.

To the Editor of the Chemical News.

Sir,—Having prepared some mercuric oxalate with the object of studying its properties, I found it to be explosive when rubbed in a mortar, evolving, at the same time, a poisonous vapour, which irritates the throat and occasions coughing. By the action of heat it produces a slight crackling noise, and deposits metallic mercury.

I have not had time to study the reaction which takes place when this substance is heated, but I think it probable that it becomes decomposed into mercury and carbonic anhydride, thus—

$$\left.\begin{matrix} C_2O_2'' \\ Hg'' \end{matrix}\right\} O_2 = Hg + 2CO_2.$$

I am not aware that this property with which mercuric oxalate is endowed is generally known.

I am, &c.

Joseph Richardson, jun., F.C.S.

16, Dawson Street, Manchester, January 1, 1867.

Recovery of Spent Manganese.

To the Editor of the Chemical News.

Sir,—I take the liberty of inquiring if any readers of the Chemical News could inform me whether there have ever been any proposals for recovering binoxide of manganese from still liquor by means of carbonate of lime, other than Dunlop's patent; and if so, who, and where to find particulars? An answer will greatly oblige.

I am, &c. MnO_2.

Determination of Phosphates.

To the Editor of the Chemical News.

Sir,—Can you not do something to rescue chemical science from the not very creditable position occupied in connexion with what is called commercial analysis? "High" and "low" analysts of phosphates ought not to exist. After several years' experience as a manufacturer, I know well that to buy by analyst A. and sell by analyst B. is often a losing game. To buy by analyst B., and to get my products analysed by him before sending them out, and to let my customers send a specimen to analyst A., is always safe; but should they send to analyst C. I am very likely to get a complaint that my superphosphate is "not up to the mark." In practice, when samples of superphosphate which contain the highest percentage—say 35 to 38 per cent. of soluble phosphate and 2 or 3 of insoluble—are analysed by two different men—a "high" and a "low" analyst—we get similar reports; but with about 25 per cent. soluble, the difference is constant—viz., 2 to $2\frac{1}{2}$ per cent. If you, Mr. Editor, were inclined to ventilate this matter, we should, perhaps, ultimately get a "broad" view of the question, quite as correct as either the "high" or the "low" creed. I am, &c.

Smatterer.

Alloys of Magnesium.

To the Editor of the Chemical News.

Sir,—In your report of the proceedings of the Chemical Society, December 6, I observe some misapprehensions on the subject of alloys of magnesium.

1st. It is stated that I brought magnesium wire into contact with the primary metals, &c. It was not magnesium wire that I used, but pure cylindrical bars of magnesium in most cases, and magnesium filings, freshly filed from cylindrical bars, in other cases.

nd. Your readers, from the report in question, might conclude that I stated that the zinc alloy was an exception to the rule of the brittleness and the readily tarnishing properties of magnesium alloys; but, although the zinc alloy seems to be an exception to the easily tarnishing character, and may be kept exposed a long time to the air without tarnishing, it is not, however, an exception to the brittle character of magnesium alloys, as it is exceedingly brittle. Some of the zinc alloy has remained free from tarnish more than six months.

3rd. The silicide of magnesium which is formed together with some oxide of magnesium, when finely powdered silica is heated to redness with an excess of magnesium filings in a current of dry hydrogen, is only slowly decomposed by water, but when treated with dilute or concentrated HCl it gives violent reaction and copious evolution of the spontaneous inflammable siliciuretted hydrogen.

4th. It is not the magnesium amalgam which I suggested the possibility of a substitute for hydrargyrum cum cretâ, but the oxidised portion of the amalgam, which is formed on exposure to the air—a brownish-black oxide of Hg and oxide of Mg + some water which separates from the excess of mercury. The stability of this oxidised compound of Hg and Mg is yet open for further investigation. Hitherto many objections have been made to the employment of hydrargyrum cum cretâ, and also to the hydrargyrum cum magnesiâ; the latter of which is now seldom, if ever, prescribed as a medicine, from the fact that the mercury is more mechanically mixed than chemically combined by the present mode of preparing these compounds—namely, by triturating Hg with chalk, or Hg with magnesia, in a mortar. But could these compounds be prepared so as to obtain a more uniform and chemically combined oxidised state of the mercury? The probability is that the preparation of more valuable compounds of mercury with chalk, and Hg with Mg, would be added to our British Pharmacopœia than those above referred to. I stated that the preparation of a compound of $Hg_2O + MgO$ by oxidation of the "magnesium amalgam" would be difficult, but that this difficulty may be overcome by experience, which consists in separating the finely divided Hg from the oxidised product, as the great density of the Hg_2O and the light density of MgO cannot be uniformly and well washed and decanted off from the Hg. In my paper I have given an analysis of some of the oxidised product which was separated first by pressure in chamois leather, then rubbed with a stout spatula of tin upon a smooth surface. I am, &c.

J. Parkinson.

December 26, 1866.

[We insert this letter, inasmuch as it contains some further details relating to the magnesium alloys, but we do not hold that it is incorrect to apply the term *wire* to the small rods of magnesium which, as commonly sold, are six inches long and *an eighth of an inch* in diameter. The same dimensions in brass, copper, or silver, would always be called *wire;* and iron "telegraph wire" is considerably thicker. Then, again, the diminutive character of the specimens exhibited by Mr. Parkinson would be inconsistent with the use of substantial *bars* of magnesium. The author's crude suggestions respecting the magnesium amalgams and the employment in medicine of an indefinite oxidised portion formed from it by exposure to the air, appear altogether unworthy of attention until the "further investigation" shall have been made. The paper and the analysis alluded to by the author, in his last paragraph, were not forthcoming at the meeting, and many of his statements were inaudible.—Ed. *C. N.*]

Blasting with Gun-cotton.

To the Editor of the Chemical News.

Sir,—In your impression of the 7th instant, a correspondent, "H.S.P.," asks for information upon the method employed in using gun-cotton for blasting operations. A short time since I made some experiments upon this subject for the purpose of comparing the effect produced by the explosion of gun-cotton with that of gunpowder. The rock I experimented upon was a syenitic granite in the island of Jersey, exceedingly hard, and most difficult to blast. The method I adopted in using the gun-cotton was precisely the same as when gunpowder was used. A boring was made in the usual manner by the repeated blows of sledge-hammers upon a steel-tipped chisel which was turned round a few degrees after each blow. From time to time the powdered rock has to be extracted from the boring. The process is an exceedingly slow one, as it takes three men about six days to bore a hole 15 feet deep and 3 inches in diameter. The required depth having been obtained, the boring is thoroughly

cleaned out by a rod of iron with a roll of tow at its extremity; everything is then ready for introducing the gun-cotton. The gun-cotton I employed was manufactured by Messrs. Prentice; it is made into a kind of rope, of different diameters, and in lengths of about 6 inches; each length is covered with parchment, a hole being left through the centre of the cartridge. In a boring of the depth above mentioned, of course a number of these cartridges have to be used; they are then connected by pieces of patent fuse. In a boring of 15 feet depth, about 6 feet from the surface is tamped in the usual manner with clay, a fuse passing from the uppermost cartridge to the surface. Great care is requisite in tamping. Immediately above the top cartridge a little hay or tow ought to be placed, as accidents have occasionally happened through the charge prematurely exploding, probably by a spark produced by the friction of fragments of rock during the blows given with the tamping-rod. The charge being thus placed, everything is ready for the blast; a light is applied to the extremity of the fuse, and while it is burning down to the gun-cotton, all hands withdraw to some safe retreat, in case of a shower of fragments of rock.

As to the effect produced by gun-cotton in blasting such hard rock as I experimented upon, I am of opinion that, in the form in which I used it, it cannot be compared to gunpowder when large blasts are required. I tried several small blasts, with a single length of the gun-cotton rope, and I found that more rock was moved than when a quantity of gunpowder of an equal value was used; but with larger blasts, in which several lengths of the gun-cotton rope joined together by the fuse were used, the effect produced was not so great as that produced by an equivalent quantity (pecuniarily) of gunpowder. I accounted for this by supposing that the whole length of gun-cotton rope did not explode simultaneously, but that each cartridge exploded at a minute interval after the one immediately above it, and therefore the explosive force was much diminished. There are many advantages in favour of gun-cotton—for instance, it is, bulk for bulk, much stronger than gunpowder, and therefore a great saving in the cost of boring is effected by its use; and in tunnelling or underground blasting, it is invaluable on account of the absence of smoke after the blast. I found that the gun-cotton shattered the rock more than gunpowder—an advantage, perhaps, in mining and excavating operations, but a disadvantage in quarrying where large blocks of stone are required. I am, &c.

T. A. Pooley, B.Sc., F.C.S.

MISCELLANEOUS.

Dangerous Toys.—Everybody must have noticed the growing tendency that there has been of late years on the part of manufacturers of almost every description to invest their wares with a spurious scientific value. Such methods of increasing business are not particularly mischievous, and the more sensible portion of the public has ceased to be misled by them, and looks on them merely as tricks of trade. Within the last two or three years, however, it has been discovered that certain dangerous chemical compounds could be transformed into so-called scientific toys, to amuse, burn, and poison the children of the public. The mania began with Pharaoh s-serpents, which, although harmless enough when exhibited in a well-ventilated lecture theatre, emitted mercurial fumes enough, when shown in a small parlour, to salivate those present. A young prince, when they first appeared in Paris, mistook one for a *bon-bon*, swallowed it, and just escaped with his life; the article being covered with tinfoil, in order, no doubt, to make it look as much like a chocolate pastille as possible. The "Devil's-tears" are much more likely to do serious mischief than the Pharaoh's-serpents. They consist of a little cotton-wool oval capsule open at one end, and covered with a thick layer of varnish of some kind to give it solidity. At a small distance, they look precisely like a red sweetmeat, or one of the berries of the hawthorn. Indeed, out of five children who were separately asked to say what they were, three answered that they were sweets, and two said they were berries. Inside the capsule is a little pill of coarse paste made up apparently of potassium and heavy coal oil. When thrown into water, the potassium of course inflames, rushes about the surface in the usual style, and finishes the display by sending several red-hot globules of potassic hydrate into the faces of the admiring spectators. But let any of our readers imagine the fearful results of a child swallowing one of these devil's-tears, which are so like sweetmeats and berries. On the tube containing them there is the *naïve* direction, "Do not put them in the mouth." Now, if there is one thing especially calculated to make a child swallow anything, it is to tell him not to put it in his mouth. Even if these mischievous capsules are not swallowed, the danger of inflicting fearful burns on damp fingers still remains. Of course, the "inventor" of the devil's-tears has had a number of imitators who have gone to work more clumsily, cheaply, and dangerously. The Juno's-tears, witches'-tears, and half-a-dozen other imitations are simply little pieces of sodium done up in corked tubes without any protecting liquid. The directions given, of course, prescribe hot water for the experiment, but nothing is said *apropos* of feeding on the contents of the tubes. The inventor of the devil's-tears is Barnett, the same individual who first introduced the Pharaoh's-serpents. On the label of the bottle there is the following singular announcement:—"Barnett, patentee (complete specification in England, France, Belgium, America, &c)." Does Mr. Barnett really mean to tell us that he has patented the ignition of potassium by throwing it into water? Are we to see this dear old experiment no more at popular lectures? Or is it only to take place by his special permission? Why does he not also patent the combustion of charcoal, iron-wire, sulphur, and phosphorus in oxygen? As yet, we fancy, the sale of these dangerous toys has not been very great; Christmas, however, has now arrived, with its holidays, parties, and increased pocket-money. Hundreds of these potassium pellets will be purchased, and these little red balls, hardly distinguishable from sweets and berries, will be rolling about half the nursery floors in the kingdom. Have the police no power to stop the sale of such articles? A tainted leg of mutton is liable to be seized and the butcher fined, a poor errand-boy who lets off a squib in the street is handed over to the police, and yet "devil's-tears" are sold with impunity.

Use of Sodium in Metallurgy of Silver.—Mr. Kustel's opinion, that sodium is "too expensive" to be applicable, is untenable in the extreme. As a *reductio ad absurdum*, let us suppose that it were necessary, as he believes, in the translation to amalgam of the silver in an ore (the chloride, for instance) to use an equivalent quantity of sodium; then, as 1 lb. avoirdupois of sodium is equivalent to 4·7 lbs. of silver, or about 75 oz., worth at $1·29 per oz. $96·75, it is necessary to show cause why the cost of sodium must approach this latter sum (in coin) per lb., to prove its use even for "decomposing" chloride of silver unprofitable, and to give any currency to this "idea" of Mr. Kustel's.—*Henry Wurtz.*

Action of Sodium Amalgam on Silver Ores.—I recommend practical metallurgists (all, of course, familiar with the tardy and tedious action of iron on moist chloride of silver) to bray together in a mortar some iron filings, quicksilver, and precipitated chloride of silver, adding, meanwhile, a small quantity of sodium amalgam, the sodium in which, however, may be but a small fraction of that equivalent to the chloride. The almost instanta-

neous result will be a mass of pasty or nearly solid silver amalgam. If such phenomena as this are to be ignored, or pooh-poohed, as signifying nothing, and having no bearing on the working of silver ores, I have but to submit respectfully that this seems like carrying an assumption of practicality (?), and an affectation of contempt for science considerably beyond the limits of common sense.—*Henry Wurtz.*

Sodium Amalgamation in Colorado.—Letters have been received from Mr. Bruce, who is one of the oldest and most reliable of the Colorado mill men. In one he says, after relating the above result in his battery—"I am putting into the mill one of the Bertola pans, and will have it running this week. I expect big results from the amalgam with the pan. I think every mill in the mountains would use the amalgam if anybody had it to sell." Later, under date July 17, Bruce says—"Everybody believes the amalgam to be the best thing yet, and everybody would buy it were it for sale here. You can rest assured the amalgam is all right. Last week I used ¼ oz. of amalgam to 2 lbs. of quick (quicksilver), and I think ½ oz. to 2lbs. is better than 8 oz. to 2 lbs. quick." Under a still later date, July 30, he says—"The amalgam is doing nicely for me. The longer I run the mill with it, the better I like it. The ore is what we call white quartz, with some copper and white iron pyrites. The Black Hawk Company like the amalgam very much, and will use it all the time. Col. Grafflin has some to try on his ore soon. I will send reports from him as soon as I can get them. Every one thinks well of the amalgam who has had it to use, with two or three exceptions, and I think they did not care to use it."—*Henry Wurtz.*

Preparation of Chromate of Copper,* by M. Stinde.—Under the name of chromate of copper a green liquid is sold, consisting of a solution of neutral chromate of copper in ammonia. It is much used in dyeing, and is prepared by the following method:—Dissolve

Bichromate of potash	1 p.
In hot water	20
And add sulphate of copper	2

keeping the temperature near the boiling-point, and supplying the place of the evaporated water by fresh hot water. When all is dissolved, add gradually a solution prepared with

Crystallised carbonate of soda . . .	1 p.
Boiling water	2

Redissolve the first-formed precipitate by shaking, and at the same time carbonic acid will be disengaged; when no more of the latter is evolved, stop the shaking; a brown precipitate will have been formed, consisting of chromate of copper, which allow to deposit, and decant. Wash the precipitate three times in warm water so as to remove the sulphate of potash, then with cold water; afterwards dry, and add ammonia of 0·91 of density. Any excess of ammonia must be avoided, and it should be aded in small quantities at a time, as the precipitate is very soluble. Filter quickly through flannel, reduce by evaporation to 25° B., and preserve in closed vessels.

On a Mineral of Yttria in the Alps,† by M. Wartha.—Under the name of wiserine, an yttriferous mineral has been described, which has been found in the Haut-Valaise, as well as on Mont Fibia, south-west of the Hospital of Saint-Gothard. It crystallises in square-based prisms similar to zircon. It was supposed to contain silica and titanic acid, but M. Wartha has found this to be an error, and that, excepting a little iron, it contains only phosphoric acid and yttria. It is a phosphate of yttria, identical with the xenotime of Berzelius, and it is of particular interest on account of its Alpine origin, as yttria has hitherto been vainly looked for among the various Swiss minerals.

Meetings for the Week.

Tuesday, January 8, 1867.
Royal Institution, 3 p.m. Professor Frankland, "*On the Chemistry of Gases.*" (Juvenile Lectures.)
Royal Medical and Chirurgical, 8½ p.m.
Photographic Society, 8 p.m.
Ethnological Society, 8 p.m.
Wednesday, January 9.
Microscopical Society, 8 p.m.
Thursday, January 10.
Royal Society, 8½ p.m.
Friday, January 11.
Astronomical Society, 8 p.m.

ANSWERS TO CORRESPONDENTS.

NOTICE.

We have great pleasure in announcing that the Abbé Moigno has undertaken to forward each week a letter containing the scientific news of the Continent, the first of which will appear in our next.

The present volume of the Chemical News *will contain an illustrated series of papers on the Application of the Blowpipe to Quantitative Analysis and Assaying, by David Forbes, F.R.S. Papers on the Synthesis of Organic Substances, and their Application to Manufactures, by Dr. F. Crace Calvert, F.R.S. Also, a full account of Professor Stas's recent Memoir on Atomic Weights, with a detailed description of the processes employed. An entirely new and complete set of Tables for Qualitative Analysis, by Dr. Hofmann, F.R.S., and some articles on Cyanogen, by Dr. Odling, F.R.S., are also in preparation, and will appear as soon as ready.*

*** In publishing letters from our Correspondents we do not thereby adopt the views of the writers. Our intention to give both sides of a question will frequently oblige us to publish opinions with which we do not agree.

*** All *Editorial Communications* are to be addressed to the Editor, and *Advertisements* and *Business Communications* to the Publisher, at the Office, 1, Wine Office Court, Fleet Street, London, E.C. *Private* letters for the Editor must be so marked.

Vol. XIV. of the Chemical News, containing a copious Index, is now ready, price 11s. 6d., by post, 11s. 6d., handsomely bound in cloth, gold-lettered. The cases for binding may be obtained at our Office, price 1s. 6d. Subscribers may have their copies bound for 2s. 6d. if sent to our Office, or, if accompanied by a cloth case, for 1s. Vols. I., II., and VII. are out of print. All the others are kept in stock. Vol. XV. commences to-day, and will be complete in 26 numbers.

C. H. H.—"Estimating Nitrogen by Chloride of Zinc," by James Walker, is contained in vol. ii., No. 51, p. 230.

CsS2 asks whether there is any apparatus at present in use for the extraction of grease by bisulphide of carbon, and, if so, who are the makers of such apparatus.

Obtaining Steatite.—*J. C.* wishes to know where he can obtain a few tons of good steatite, and at what price.

Utilisation of Gas Liquor.—A correspondent who has the management of a small gas works in a village, and does not know the value of the ammoniacal water, will feel greatly obliged if any one will inform him of the best plan of utilising it.

Sydney Heely.—A full description of the construction and powers of Wilde's magneto-electric machine, written by Mr. Crookes, will be found in the October number of the *Quarterly Journal of Science*, published by Churchill.

J. A. asks if any one can inform him of the exact quantity of tar or crude oil which manufacturers in this country obtain from one ton of Boghead gas coal, and of the quantities of paraffin and other oily products they obtain from 100 gallons of crude oil. Probably some of our correspondents may be able to furnish the information; if so, we shall feel obliged.

Engineer.—The unpleasant smell is not the only objection to the use of coal or coke containing sulphur. It has been found that when such fuel is burnt under steam boilers the iron is rapidly corroded by the sulphur.

"*Fire-damp.*"—Mr. Ansell has written to say that each and every statement made in the paragraph in the *Mining Journal* is simply untrue. A full account of the "Indicator," written by Mr. Ansell, will be found in the Chemical News, Vol. XII. p. 280.

Received.—Dr. Letheby: B. W. G.

Books Received.—"Braithwaite's Retrospect," 1866; "Dictionary of Chemistry," Part XXXVII., Silica—Sodium.

THE SUSPENSION OF THE STORM SIGNALS.

The use of storm warnings at various stations on the coast for the purpose of enabling seamen to prepare for the approach of bad weather was, as is well known, originated by the late Admiral Fitzroy, and by him was brought to a high state of practical efficiency. Since his death the system has been continued under the direction of Mr. Babington; and it is a sufficient proof of the ability with which this undoubtedly difficult subject has been managed, that, so far as is known, no complaints have been made by any of those most interested in its operation.

The opinion of the value of these signals that was so generally entertained makes their sudden stoppage appear the more extraordinary. The Board of Trade were guided in their decision by the recommendation of the President and Council of the Royal Society, who are of opinion that "at present these warnings are founded upon rules mainly empirical, and therefore should not be issued under the superintendence of the scientific body to whom the discussion of meteorological observations will be committed." Many objections to this view of the subject at once present themselves, without regarding the obvious fact that, before taking so decided a step, the Board of Trade should at least have consulted the wishes and opinions of those chiefly concerned — viz., the fishermen and owners of small coasting vessels, and to whom a knowledge of the probable changes of weather is of paramount importance. It cannot be denied that the rules of this branch of science are at present mainly empirical, but this is an evil which would daily tend to remedy itself; and if on this account the duty of carrying them out were considered to be derogatory to the scientific body entrusted with the management of meteorological observations, this would point, not to the abandonment of the system, but to its being relegated to some more suitable department. As was forcibly urged by Mr. Baxendell, at a recent meeting of the Manchester Literary and Philosophical Society, in the early stage of every science its rules are mainly empirical; but it has never before been stated that therefore we should not avail ourselves of the knowledge we possess. The correction of the compasses in iron ships is based upon somewhat empirical rules, and mistakes are sometimes made, but are we on that account to neglect to take any such precaution? Reasoning of this kind, if logically adhered to, would lead to the entire abandonment of the use of medicine, which, we think, no one would venture to assert is administered according to strictly scientific laws. It is doubtless a misfortune that the rules of meteorology are not at present mathematically accurate, but the surest way of making them so would be to carefully compare the predictions with the phenomena that actually occur, and, by gradually eliminating disturbing causes, to plant the subject upon a firm scientific basis.

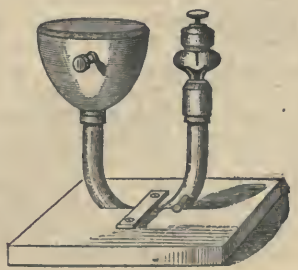
We trust that the disappointment so generally felt at this retrograde movement on the part of the Board of Trade will have the effect of making them reconsider their determination, and that, directing their attention to the good it has done, rather than to its present want of scientific symmetry, they may continue a system which has become familiar to, and met with the approval of, the country, and which seems, more almost than any other undertaking, calculated to advance the science of meteorology.

ANSELL'S FIRE-DAMP INDICATOR FOR COAL MINES.

Recent events have given great interest to the invention of Mr. Ansell, to which attention was called in Vol. XII. p. 280 of the Chemical News. Although those descriptions were at that time perfectly correct, it is hardly to be expected that Mr. Ansell should have left the matter where it then was, especially as he has largely tested those instruments in coal pits in the positions where they would be required for use. They entirely answered the purpose for which they were proposed—namely, the indication of fire-damp, when accumulating either slowly or rapidly; but there were objections which on the face of them were serious, and which by practical men were considered fatal, unless under exceptional circumstances. Guided by the opinions then expressed by those most concerned, Mr. Ansell endeavoured to find a more simple form of instrument, which could be readily understood by a workman of ordinary intelligence.

In coal pits there are many casualties — including the bulk of the accidents arising from explosion— caused by a sudden irruption of fire-damp (carburetted hydrogen) to such an extent as to render the atmosphere in even a mile of space explosive in a few minutes, and there are cases on record where an enormous space has been so polluted in a few seconds; but the common event is to find that a fall of roof, or the breaking in of a thin part in the sides or floor of a gallery, liberates an amount of gas which by mixture with the ordinary air of the pit renders the whole explosive. This mixture travels on slowly with the ventilation, till presently it meets a light, and possibly an hour after its first formation destroys many lives. In all such cases Mr. Ansell proposes to use an instrument of which Fig. 1 is a sketch.

Fig. 1.



It consists of an iron funnel provided with an iron U-tube, the end of which is closed by a piece of glass tube fixed in brass, to which one pole of a battery is attached; the upper part of this glass tube carries a brass collar, through which passes an adjusting screw, to the lower end of which is fastened a piece of copper wire with a platinum point. Mercury is poured into the iron funnel till it rises in the glass tube to a

convenient height. This mercury is allowed to find its level by the opening of a valve, when setting the instrument.

The septum is a tile of Wedgwood's ware, and closes the open part of the funnel, good sealing wax being the best cement for securing it in its place. The other battery wire is connected with the instrument, so that, if diffusion take place, the mercury is pressed up against the platinum point, and thus communication is established. Mr. Ansell has found that this instrument gives warning in four seconds if the mixture of gas be still below the point of explosion; but, by adjusting the point so that there is not more than the thickness of a shilling between it and the mercury, a dangerous irruption may make itself known in two seconds.

A source of great danger is that state of the pit which arises from the gradual bleeding of gas from the coal. As one walks in a pit one hears a continual click, somewhat like the noise of a cricket. In some pits this may arise from the settling down of the shale and cracking of the coal, but the experienced ear soon knows the difference. Should any obstruction arise to the ventilation, this bleeding very gradually raises the atmosphere from zero (the point of purity) to the point of explosion; or it may be that a gradual fall of the barometer admits of the oozing out of gas either from a goaf or from the mass of coal, and this, although very minute, may be to such an extent as to render explosive the whole air of the pit, if the ventilation be not very good. There are parts of the pit where gas may so accumulate in half an hour; others where it may be two hours, and again others a whole day, in rising to a dangerous mixture. To meet such cases, Mr. Ansell used, in the first instance, an india-rubber balloon; but this, although perfectly good for its purpose, was too fragile. Therefore, he has abandoned that plan, and he now uses white Sicilian marble, and by regulating the thickness avoids the evil of effusion to such an extent that he can, and does, in the pit practically show these gradual accumulations. Mr. Ansell has found that by replacing the Wedgwood ware tile (in Fig. 1) with marble of a quarter of an inch thick, he can show the presence of an explosive mixture of fire-damp and air which has been half an hour in forming, or by using marble half an inch thick he shows if it has been two hours rising from zero to the explosive point. In all such cases, notice, if it be so desired, may be given before the mixture becomes explosive, the warning being continued for a considerable time even if the atmosphere does not become more foul. It must, however, be understood that the very circumstances which admit of the air becoming "fouled" to the extent of 10 per cent. also admit of its going on till 50 or more per cent. has been reached, always remembering that these instruments are to be fixed high up in the roadway or goaf, and that the gas accumulates there notwithstanding the law of diffusion. It is no uncommon thing to find 30 per cent. of gas next the roof, at six inches lower 20 per cent., and at fifteen inches no gas at all. The cause of this will be discussed on some other occasion.

It is proposed to fix the instruments side by side, one for *sudden* and the other for *slow* accumulations, in pigeon-holes cast in the iron props used to support the roof, these pigeon-holes being clear all through so that the gas can surround the instruments or sweep over them; for the gas as it occurs in the pit is very curious in its habits, and, from causes too minute to enumerate here, it "goes away" from a spot with very little "disturbance." The pigeon-holes being formed in iron posts would protect the instruments from falling roof, &c., while grooves may be cast in the sides of these posts for the telegraphic wires. It has been objected by some that these instruments would cause greater destruction of life than now obtains; but these persons forget that they are not intended to displace other means of safeguard. They are simply proposed as additional means of knowledge.

For the indication of carbonic acid Mr. Ansell makes a necessary alteration, which will be seen in Fig. 2.

Fig. 2.

This hardly needs description, for it will be seen at a glance that the circuit is completed by the rising of the mercury to the wire within the precincts of the closed chamber formed by the neck of the funnel, and is adjusted for use by turning the base on which it stands, when a cork rises against a leather bag, and presses the mercury up to the required height. Whether marble will stand long without disintegration by carbonic acid has to be determined; if not, it can be replaced by another septum. This instrument is proposed for use in those mines where carbonic acid becomes a dangerous substance for the miner. It has been sought by the French wine-growers as a means of telling the time of the commencement of fermentation, and it seems probable that the English brewers will use it for a similar purpose.

In the event of fire-damp being known to exist, either when found by the fixed indicators or by the safety lamps, Mr. Ansell proposes for the use of the miner, the manager, or his deputy, an aneroid indicator, described in detail at page 280, Vol. XII., of the Chemical News. Some persons who have not cared to read the description, or to make themselves acquainted with the use for which this instrument is made, imagine that it possesses strange properties. It is therefore necessary to say that it is not used for the detection of gas in the pit. The intention of this particular instrument is that it shall be used to determine the amount per cent. of fire-damp or carbonic acid gas where they are known or suspected to exist; and for these purposes it must be used rigidly according to the instructions given with it, not according to the fancy of the user *or as he thinks it should be used.* It must be taken, with its brass cap still on, into the neighbourhood of the suspected atmosphere, and allowed to remain there till it has acquired the temperature of that place; this usually requires a few minutes (say five). The valve must then be opened to allow it to find the true zero of that altitude. Then the valve must be closed, and the index watched for a few seconds to see if it be stationary, and if it be so then the brass cap must be removed, and the indicator held by its handle in the suspected place for the time specified on the instrument—about one minute.

It must be mentioned that the same amount per cent. of fire-damp in different mines requires a varying time for diffusion through the same tile. The cause of this is at present unknown, but it is under investigation. This variation of time is from 45 to 60 seconds, but in the same pit it is invariably of a uniform time, so that once determined there is no trouble. That this is a property of the gas is proved by the fact that 10 per cent. of gas in one pit will explode violently while 10 per cent. in another pit explodes with much less violence. The underviewers call one a *sharp* gas and the other a *slow* gas or fire, and the difference is perfectly well marked if observed for a few times in the lamp.

A mine, to be well ventilated, should be so supplied with air that a considerable irruption should be diluted below the point of explosion. Ventilation which is only sufficient for ordinary occasions must be considered entirely insufficient.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On the Nature of the Gas which is given off from Fresh Charcoal when immersed in Water, by William Skey, *Analyst to the Geological Survey, New Zealand.*

As far as I can learn, it is generally supposed that the gas escaping from charcoal when put in contact with water is common air, and, indeed, I am not aware that any different opinions are, or ever have been, entertained. I therefore beg to state the results of certain investigations of mine upon this gas, which show it to have a different composition from that assigned to it.

I shall begin by stating that I was led to these investigations by observing, in the course of some experiments in connexion with the absorption of charcoal, that as large a volume of gas was given off from recently ignited charcoal, when means had been taken to exclude the presence of air during the cooling down of the red-hot charcoal to ordinary temperatures, as where it had been suffered to cool in contact with air. Thus, when a piece of red-hot charcoal was plunged into mercury, and, after cooling, suffered to rise directly into water subsequently put upon the mercury, as large a volume of gas is evolved as if it had been cooled in air.

From this circumstance it appeared to be in the highest degree improbable that any oxygen should enter into the composition of this gas, the affinities of charcoal at high temperatures for oxygen being so great as to render it impossible that it could be held so loosely, by an act, as it were, of mechanical absorption, as to be capable of being displaced by water.

Nor is the quantity of gas given off in this manner by charcoal to water so small that it can be accounted for by taking into consideration the effects of mechanical absorption upon the highly rarefied air left intact as a residue in the pores of the charcoal by its sudden refrigeration. Thus the quantity of gas given off by one volume of the charcoal of the manuka and pine was found to be no less than three and a half volumes.

These considerations suggested an attempt to discover—

1st. The nature of the gas.

2nd. The circumstances to which this capacity of charcoal to evolve gas is related.

Respecting the nature of the gas, it was found to be insoluble in water—at least to any very appreciable extent. Mixed with air, it is uninflammable; while its volume does not appear to be the least diminished by prolonged contact with hydrate of potash or with a solution of potassio-tartrate of protoxide of iron; the green colour of the solution, of course, remaining unchanged. Its specific gravity was found to be ·99, after making the proper deduction for the amount of aqueous vapour it would have retained by contact with the water employed to liberate it at the temperature it sustained.

From these facts it would appear the gas under consideration is nitrogen. I am aware the specific gravity is a little too high, but the excess is quite within the limits of error. I should be prepared to allow for the use of the clumsy and ill-adapted apparatus I had to employ for the purpose.

In prosecuting the second part of the inquiry, it was found that this property of recently ignited charcoal remained to it, no matter how frequently it was ignited and immersed in water.

Nor is a full ignition absolutely necessary to secure this property to charcoal; for if, after an immersion in water for forty-eight hours (by which time the evolution of gas has well ceased), it is subjected to a temperature just under that at which luminosity commences, then cooled under mercury, and suffered to rise into water, as large a volume of gas is evolved as before. Moreover, the application of a white heat appears to confer this property upon charcoal to the same degree as a red heat.

It was next ascertained that, by igniting charcoal, that had been previously in contact with water, in common salt, there was not the least evolution of gas on treating the fused mass with water.

The behaviour of recently ignited charcoal with different liquids was next observed, when it was found that, if it was suffered to rise into kerosene oil or oil of turpentine after being cooled under mercury, there was not the least evolution of gas, nor yet if, for the oil, concentrated sulphuric acid or saturated solution of caustic potash or chloride of calcium was substituted; but the liberation of gas was instantly determined by a subsequent treatment with water. But in concentrated solution of ammonia, carbonate of ammonia, nitric acid, alcohol, ether, or bisulphide of carbon, the yield of gas appeared to be quite as great as in water.

Red-hot charcoal plunged into kerosene oil, bisulphide of carbon, or concentrated sulphuric acid, and afterwards immersed in water, was incapable of affording gas.

(To be continued.)

TECHNICAL CHEMISTRY.

The Magnetic Polarity of Rifles, by John Spiller, *F.C.S.*

Having recently made an observation in this direction which may prove interesting to some of your readers, I am desirous of knowing from others the results of firing under different circumstances from those in which we are placed.

I find that all the long Enfield barrels of the arms in the possession of the volunteers of my company exhibit magnetic polarity, as the result of the violent and repeated concussions attending their discharge in a direction parallel to the magnetic meridian. The Royal Arsenal range runs nearly north and south, and our rifles when in use are always pointed either due north, or a few degrees towards the west—in fact, nearly in the direction indicated by a compass needle,—so that the repeated shocks brought about by the explosion of the powder may be considered equivalent to so many hard blows from a hammer, which are known to have a

similar effect. The magnetic character appears to be permanent, which would not be the case if the gun-barrels were of the softest description of malleable iron, and the region of the breech is in every instance possessed of north polarity, since it strongly attracts the south pole of the compass needle. These effects should not be noticed at all, or only to an inferior degree, in arms ordinarily fired in directions east and west; and I imagine that by reversing our usual practice, if it were possible, and firing towards the south, the indications of polarity would be changed.

The great masses of wrought iron entering into the construction of the heavy rifled ordnance do not, so far as my observations have extended, exhibit like results, although fired for proof at the selfsame range; neither do the old cast-iron guns. I am well aware that it is scarcely possible to find rods of hard iron or steel destitute of magnetic polarity, but the indications to which I now allude are so well marked, and are, moreover, coincident; they must therefore be the result of the operation of a general law.

The foregoing observation seems to me to have a parallel in the remarkable instance of the polarity of Her Majesty's ironclad *Northumberland*, built last year at Millwall. This vessel was placed due north and south during her construction, and the repeated vibrations to which she was subject whilst in that position induced a condition of polarity which demanded a subsequent operation for the purpose of demagnetising her. No such practical inconvenience arose in the case of the iron steamship *Great Eastern*, which was built in the same yard, but in a position at right angles to the former, or nearly due east and west.

Chemical Department, Woolwich, Jan. 7.

FOREIGN SCIENCE.

(From our own Correspondent.)*

Paris, January 8, 1867.

The Imperial Commission has conceded in the interior of the Champ de Mars—that is to say, on the grounds of the Exhibition—an eligible spot of ground, situated at the side of the International Club, with the exclusive privilege of giving lectures day or night. The entire edifice is to cost 2000*l.*, and is to be erected before April 1. The amphitheatre fitted with seats in steps will accommodate 500 seated auditors. We will not publish to-day the very varied syllabus of this course of lectures, but content ourselves with stating that it is of a nature to satisfy amply governments and exhibitors, and that the celebrities of science and national and foreign industry will certainly take part therein. We may also add that those whose exhibits are the largest or most novel can put down their names for one or more lectures, so as to bring the merits of their inventions or produce more into notice. Along with Messrs. Pierre Petit, concessionist of photography to the Commission, and Ducoin, we shall take a very active part in this fine enterprise, which will add, we hope, to the interest and *éclat* of this great struggle among nations, united in a sentiment of a generous rivalry of peace and conciliation.

M. Berthelot terminates, in the last number of the *Annales de Chimie et de Physique*, a long series of papers upon hydrocarbons, with the following considerations, which we hasten to place before our readers:—"The carburets, petroleums, and bitumens, which are often disengaged in great abundance from the crust of the earth in a continual stream, and arise from depths which seem to exceed those of stratified formations—do these combustibles, I say, always necessarily result from the decomposition of a pre-existing organic substance? Is this the case with the carburets so often observed in eruptions and volcanic emanations, and to which M. Ch. Saint-Claire Deville has called attention during these last years? Lastly, should a similar origin be assigned to the carbonaceous matters and carburetted hydrogen contained in certain meteorites, and which appear to have had an origin foreign to our planet? These are questions upon which the opinions of several distinguished geologists are not yet fixed. Without pretending to decide a question which requires the assistance of observations foreign to chemical synthesis, it appears to me to be interesting to show how natural hydrocarbons could have been formed synthetically—I mean by purely mineral reactions, similar to those which geologists make intervene between the substances contained in the interior of the globe and the consecutive materials of its envelope. The hypothesis recently put forth by M. Daubrée, that the terrestrial mass contains free alkaline metals in its interior, joined to the experiments which I have made lately, lead almost necessarily to a mode of explaining the formation of hydrocarbons—in fact, the carbonic acid, everywhere infiltrated into the crust of the earth, coming in contact with the alkaline metals, forms acetylides. According to my experiments, these same acetylides would result also from the contact of earthy carbonates with alkaline metals, even below a dull red heat. Now, these alkaline acetylides once formed can be subjected to the action of steam; free acetylen would be the result, if the products were immediately withdrawn from the influence of heat, hydrogen, and other matters present. But, on account of these different conditions, the acetylen would not exist, as my recent experiments prove. In its place we obtain either the products of condensation which approach the bitumens and tars, or the products of the reaction of hydrogen upon the matters already condensed—that is to say, more hydrogenated carbides. For example, the hydrogen reacting upon the acetylen produces ethylen and hydride of ethylen. A new reaction of the hydrogen either upon the polymeres of the acetylen or upon those of the ethylen would engender formenic carbides such as constitute the American petroleums. An almost unlimited diversity in the reaction is here possible, according to the temperature and the bodies present. We can thus conceive the production by a purely mineral method of all the natural hydrocarbons. The intervention of heat, water, and alkaline metals—lastly, the tendency of the carbides to unite together so as to form matters more condensed, suffices to account for the formation of these curious compounds. This formation can also be effected in a continuous manner, since the reactions which produce it are incessantly renewed."

M. Berthelot is truly astonishing. What force of conception, what power of labour, what rapidity of expression! These last memoirs occupy no less than a hundred pages of the December number of the *Annales de Chimie et de Physique*.

The first form given by M. Mille to his petroleum lamp—an external recipient in metal, an internal one in wire-gauze, a sponge occupying the centre of the vase, and steeped in essence of petroleum—has undergone a very simple modification, under the hands of Messrs. Leplay and Noël, 14, Rue Belzance, Paris, which will render the lamp extremely popular. This improvement consists in the addition of a round wick in contact, at one of its extremities, with the sponge wetted with the essence, and touching at its other extremity the end of a tube, through which it passes, and which forms the termination of the exterior metallic reservoir. In order to prepare the lamp,

* It gives us great satisfaction to lay before our readers the first of the promised weekly communications from the Abbé Moigno. The Abbé's opportunities for acquiring early information are very great, and his position in the scientific world is so well known that he requires no further introduction from us.

the cap is removed and the essence poured in; and when the sponge is saturated the excess of liquid is poured out, so that there is no more free essence, and were the lamp upset, none would run out, nor would there be risk of fire. This lamp is very light, and takes up little room. The flame is about equal in intensity to that of a wax or tallow candle. It burns for several hours without sensibly losing its brilliancy, and is most convenient to carry about without soiling one's clothes. To extinguish it, it is sufficient to let down the tube, which is covered with a small cap in order to prevent the liquid from evaporating during the day. The essences which supply these lamps have a density of 700 to 750 (that of water being 1000)—intermediate between the essences of a density of 650 to 700, which give gas by the spontaneous passage of atmospheric air in the cold generators of M. Mille, and the essences of 800 to 820, which is burnt in ordinary petroleum lamps. These little gazo-lamps cost from 2fr. 50c. to 6fr., according to their size and ornamentation. Messrs. Leplay and Noël sell the liquid at 1fr. the litre. If these prices seem a little high, it must be recollected that this is a new patented invention.

The *Journal de Seine-et-Oise* mentioned lately that at the meeting held on the 19th ult. by the Society of Natural Sciences of Seine-et-Oise, M. Martin de Brettes, Commandant and Professor of Artillery, had exhibited a gun on the Flobert system, which his Majesty the Emperor was much pleased with at Compiègne, and of which the cartridge is inflamed by electricity. Two small electric batteries are enclosed in the stock; their conducting wires arrive at the surface of the breech, and can be put in communication with the extremity of a platinum wire which traverses the cartridge. A simple pressure of the finger upon the trigger closes the electric circuit; the current passes; the platinum wire becomes at once redhot, and inflames the powder which surrounds it. The cartridges prepared for the needle gun carry their own priming, and a shock might inflame them; the cases are thus liable to explode and deprive the troops of their ammunition. With the new system this danger is impossible. It can, as the expense is trifling, be easily applied to guns of the ancient model. We extract this from the *Presse des Deux-Mondes*, but it seems to us impossible that our friend, M. Martin de Brettes, could have omitted to say that the honour of this new application is due to M. Trouvé, the ingenious inventor of the electric *bijoux*, to whom we have called his attention. We do not expect that the voltaic pile will become one of the essential adjuncts of carbines, but the inflaming of powder by electricity will be certainly very soon adopted for cannon.

F. Moigno.

PROCEEDINGS OF SOCIETIES.

SOCIETY OF ARTS.

On the Synthesis of Organic Substances, by Dr. F. Crace Calvert, *F.R.S., F.C.S., &c.*

The Council of the Society of Arts having again conferred upon me the honour of delivering a course of lectures on chemistry, I have deemed it advisable to lay before the members of this influential and eminently useful Society a branch of investigation and series of facts different entirely from those which I have examined on two former occasions. My first course had reference principally to the properties, the manufacture, and the application of certain classes of organic substances derived from or relating to the animal kingdom. I tried, at the same time, to impress upon the minds of my hearers the importance of studying chemistry in connexion with those branches of manufactures; and I further attempted to effect this by drawing attention to the recent improvements which chemistry had introduced: and there are, no doubt, many more improvements that science will develope in process of time. My last year's course was conceived with a view of impressing on the minds of those fond of scientific pursuits the necessity of studying chemistry not only as a separate branch of learning, but in its obvious and intimate connexions with nearly every other class of scientific investigation, such as physiology, geology, mineralogy, agriculture, natural philosophy, &c. The present course has been planned with the idea of giving an insight into that modern branch of science called organic chemistry, to show the valuable and interesting results arrived at by chemists in that department, and to impress upon my hearers the great advantages that society will derive from the progress of these researches, not only in a scientific point of view, but also as bearing upon manufactures and arts; for the manufacturers of the present day are not confined to the employment of mineral matters only in their productions, inasmuch as organic chemistry has placed at their disposal many useful substances which were quite unknown half a century ago, and no doubt many more will be brought to light by men of skill and research as their investigations proceed. This will, however, depend much on the progress of that science itself, which will show to chemists and manufacturers how to obtain from cheap and refuse matters substances which have a value; or, in other words, to produce artificially substances which now exist and are found in the organised kingdom, but the extraction of which is always costly and difficult, owing to the fact that the substance sought for is mixed with a variety of other substances which must be eliminated or destroyed before those substances, the properties of which are useful, can be made available. I shall, therefore, in this course of lectures, try to illustrate by facts the broad statement that science has enabled men already to produce artificially substances which may truly be called organic; and if science has already arrived at this triumphant result—I say "already," for organic chemistry barely dates fifty years back, and we all know that the first steps of a science are the most difficult, and first principles require the greatest effort of the human mind to unravel—if in this short space of time we have succeeded in obtaining a great number of facts by which certain laws have been revealed to us, we have reason to expect and hope that the next fifty years will bring facts and results to light which shall be as profitable, and I may say as astounding, as those which have been discovered of late years by the means of chemistry, and which have been the guidance of manufacturers to many very important applications.

Thus the volatile products obtained from coals were first employed as an illuminating agent. Science and application have gradually brought that illuminating agent to a high state of perfection, and have shown the most economical way of employing it, and the best means of availing ourselves of its illuminating power without interfering with the health and lives of those by whom it is used. Thereby a cheap and effective illuminating agent has been secured to society. At the same time as those volatile and gaseous products are generated water containing various substances is produced, and science having ascertained their nature, we find them converted into alums, sulphate of ammonia, and other commercial products extensively used in agriculture and in manufactures. Further, a dark, noisome, sticky product called tar is also extracted, which at first used to be the great drawback of gas-light manufacture. This product having been examined and studied by chemists, a most valuable series of substances has been gradually extracted and applied to useful purposes. First of all we have pitch, used most extensively for making smooth, clean, and pleasant footpaths, promenades, and even roadways; whilst some of the oily products which pass off are used to preserve the sleepers on our railways, and other materials used in building which it is desirable to preserve from decay. Another solid substance, paraffin, is also obtained, which

is now extensively used as an illuminating agent, and, when mixed with oils, as a lubricator. It has also of late been employed with marked success by Dr. Stenhouse as a substitute for caoutchouc, for preventing the permeation of damp or wet through fabrics. In addition to these, more volatile products are obtained, which were first applied to dissolve caoutchouc and other materials of the same class, and which, in their turn, were applied to a hundred useful purposes. The chemical composition of these volatile products having been further studied, means were discovered for obtaining by chemical transformation a series of colours rivalling in beauty, in cheapness, and in facility of application any dyes which were previously known to the world. Lastly, from coal tar or from coals a most powerful antiseptic agent is obtained, the value of which has been lately demonstrated in the cases of the cattle plague and the cholera. The properties of this substance have not yet been fully ascertained, but in course of time it will prove to be one of the most important yet discovered, owing to its powerful antiseptic properties, for we may consider the root of most of the ailments and diseases of mankind as derived from the decomposition or decay of some of the tissues, and it therefore follows that, in all diseases or decay whose source can be traced to the decomposition of organic matter, carbolic acid must undeniably be the most effective remedy.

Therefore it follows that the most interesting branch of organic chemistry is comprised in the title of this course of lectures, "The Synthesis and Production of Organic Substances by Artificial Means."

The perfect knowledge which chemists have obtained by analysis of the relationship of composition which exists between organic substances has enabled them of late years to produce artificially, or convert substances one into another, which they never could have succeeded in doing had they not had a clear insight into the composition and properties of substances under examination as compared with those they wished ultimately to reproduce.

It now devolves upon me to try to lay before you an outline of some of the methods which chemists have employed to ascertain the composition of an organic substance, and how they are able from that knowledge either to add certain elements to a substance so as to modify its composition and alter its properties, or to subtract certain elements and add instead of them certain others so as to produce new substances, which are identical with those which they want to reproduce or imitate. As it would be difficult for me in the course of an hour to lay before you the details of the system now employed by chemists to effect this end, I shall, therefore, try to give you an idea of that system generally by calling your attention to a new series of facts discovered by one of the most able of modern chemists—namely, the synthesis of organic substances, especially alluding to those which have reference to their reproduction by means of mineral elements; and before this lecture is over I hope you will be able to understand fully how that eminent chemist, M. Berthelot, has succeeded, by employing mineral matters, and by a series of successive chemical reactions, in producing substances which are only derived and obtainable from the organic kingdom either by being extracted direct from their sources of production by a series of chemical manipulations, or which are the result of the destruction of organic substances under the influence of heat or decay.

The first example which I shall have the pleasure of calling your attention to is a gaseous compound called acetylene, or the richest carburetted hydrogen known, for it contains four atoms of carbon for two atoms of hydrogen. Although this product exists always, but in small proportions, in common coal gas, still M. Berthelot asserts—and no doubt with truth—that its presence increases materially the brilliancy of common coal gas, owing to the large proportion of carbon it contains, and which by floating in the flame radiates light and thereby increases its brilliancy. This substance is characterised by giving, with a solution of protochloride of copper dissolved in ammonia, a beautiful coppery precipitate, which is highly explosive. Acetylene, also, when mixed with chlorine, and the mixture is exposed to the action of light, or to any flame containing chemical rays, such as those produced by the combustion of magnesium or sulphuret of carbon, gives rise to violent explosions with the production of hydrochloric acid and a deposit of carbon. This fact I wish you to notice, as it will be, further on, a means of distinguishing this substance from another, one which is the chief illuminating constituent of coal gas, and called ethylene, or heavy carburetted hydrogen. This substance (acetylene) does not exist merely in coal gas. M. Berthelot has proved it to exist in a great number of instances, and to be a constant product of the slow combustion of most organic substances.

Further, this substance offers to us a peculiar interest, for it is the first ever produced by chemists by the direct union of carbon and hydrogen. Up to the time of this discovery, chemists were acquainted with a great number of carburetted hydrogens, either obtained naturally from the organic kingdom—such, for example, as otto of roses, the essences of lemon, bergamot, cloves, neroli, and the solid substances called caoutchouc, gutta-percha, as well as a great number of others obtained through the destructive distillation of organic matters, as well as coals—such as ethylene, amylene, capolene, propylene, &c. M. Berthelot obtained acetylene (as I will show you at the end of this lecture) by passing through a glass globe a slow current of hydrogen gas, in which globe there were the two carbon points of an electrical battery in a state of incandescence, producing what is usually called the electrical light. Under this intense heat and electrical current the hydrogen introduced by him combined with the carbon of the points, and produced acetylene, which he collected by passing it through an ammoniacal solution of protochloride of copper, getting a coppery precipitate, or acetylide of copper, from which he easily isolated acetylene, thus proving to the chemical world the possibility of the artificial production of a carburetted hydrogen.

This discovery, which astonished the scientific world, was soon followed up by a series of facts most interesting to relate. M. Berthelot placed in a small flask, to which was attached a tube to give exit to any gas which might escape, some acetylide of copper, together with zinc and ammonia, and on heat being applied a chemical reaction ensued by which two atoms of hydrogen were added to acetylene, converting it into ethylene or heavy carburetted hydrogen, also called olefiant gas—a name which it derives from the fact that, about thirty years ago, some Dutch chemists having mixed this gas with chlorine and exposed the whole to diffused light, an oily fluid was produced called Dutch liquor, and the fluid having, as just stated, an oily appearance, gave rise to its being called olefiant. This gas is most interesting, owing to its being the chief component illuminating element in common coal gas, and is characterised by burning with a bright flame, with no deposit of carbon, as acetylene does, and when mixed with one equivalent of chlorine, and the mixture is left to itself for some time, the chlorine unites with the olefiant gas, producing the oily fluid above referred to, called Dutch liquor; but when mixed with two volumes of chlorine, and a lighted taper is brought in contact with them, hydochloric acid is formed, and carbon is deposited; further, it is absorbed slowly by sulphuric acid, which property, we shall see presently, M. Berthelot has most judiciously availed himself of to convert it into an organic substance. The olefiant gas, though existing in large quantities in common coal gas, cannot be isolated, owing to the numerous compounds with which it is mixed. Therefore it is necessary to adopt some chemical reaction to produce it in a pure state when its properties are desired

to be inquired into. To attain this end, one part of alcohol is mixed with three parts of vitriol or sulphuric acid, and on being applied each chemical equivalent of alcohol loses two equivalents of water; the remaining element of that alcohol, being olefiant gas, is liberated, and can be examined. What gives interest to this chemical reaction is, that whilst you thus unfold, under the influence of heat, alcohol into olefiant gas and water, you can, if we follow M. Berthelot's process—namely, of placing at the bottom of a large glass globe, a small quantity of concentrated sulphuric acid, and then fill the capacity of the large glass globe with olefiant gas, and keep the same in a constant state of agitation—you will, after having imparted to the vessel some 40,000 or 50,000 rotatory motions, find that the olefiant gas has been absorbed by the vitriol; that it will have fixed two equivalents of water, and that it will have thus converted the olefiant gas into alcohol, which can be isolated by subsequent chemical manipulations. Therefore from carbon and hydrogen you will notice that we first produced acetylene, and this substance we have converted into olefiant gas, and which in its turn has been transformed into alcohol, which alcohol you can easily convert into ordinary ether, as I shall explain to you in my next lecture, or into acetic ether, spirit of nitre, or nitric ether, &c.; or you can also by oxidising convert it into a substance called aldehyde. To convert alcohol into ether, all you have to do is to remove from alcohol one chemical proportion of water, and the elements which remain—namely, one of olefiant gas and one of water—constitute ether.

We can still further pursue these interesting transformations. For if you add four proportions of oxygen to olefiant gas, or if you fix upon alcohol by means of platinum black, or, as I have lately discovered, by means of charcoal in presence of an excess of oxygen, you will convert alcohol into acetic acid or vinegar. It therefore follows that from carbon and hydrogen mineral elements a great number of organic substances can be produced. In fact, from acetylene the following series of compounds have been obtained:—

Acetylene	can be transformed into		(C_4H_2)
Ethylene	„	„	(C_4H_4)
Aldehyde	„	„	$(C_4H_4O_2)$
Acetic acid	„	„	$(C_4H_4O_4)$
Glycolic acid	„	„	$(C_4H_4O_6)$
Oxyglycolic acid	„	„	$(C_4H_4O_8)$
Oxalic	„	„	$(C_4H_2O_8)$

(To be continued.)

ACADEMY OF SCIENCES.

December 24, 1866.

The President announced that the difference of longitude between Newfoundland and Valentia had been determined by Mr. Gould, to whom this duty was deputed by the coast survey of the United States. A preliminary calculation gave longitude of Heart's Content, Newfoundland, in respect to Valentia, 2h. 51m. 56·58. Time occupied by the electricity to pass through the cable, 0·328. These results are not final, but they will only have to undergo very minute corrections. Professor Airey, Astronomer Royal, is about to connect the station at Valentia with the Greenwich Observatory, and Newfoundland being in connexion with the mainland, we shall soon know, within a small fraction of a second of time, the longitude of the Eastern Coast of America.

"*On the General Characters of the Phenomena of Shooting Stars*," by M. Faye.

"*On the Reflection and Refraction of Light*," by M. C. Briot.

"*On the Existence of Perchloride of Lead*," by M. J. Nicklès. The author mixes excess of chloride of lead with solution of chloride of sodium, and then passes a current of washed chlorine. He thus forms a solution containing seven per cent. of $PbCl_2$. The reactions of this solution upon numerous organic and inorganic substances are given in this paper. By agitating the perchloride solution with ether and syrupy phosphoric acid, perchloroplumbic ether is produced; it has an oily consistency, and is very unstable.

"*On a New Class of Compound Ammonias*," by M. A. Wurtz. The isomerism between pseudo-amylic alcohol and ordinary amylic alcohol, which Dr. Wurtz has shown to extend to the ureas, is in this note proved to extend also to the ammonias. He has here described isoamylamine. To prepare it, pseudo-amylurea is heated for some days with very concentrated caustic potash, and then distilled from baryta. The new ammonia boils at 78·5°; its density at zero is 0·755. Like amylamine, isoamylamine possesses a strong ammoniacal odour, it mixes with water, precipitates metallic oxides, and dissolves oxide of copper. The hydrochlorate crystallises in brilliant octahedra, which are efflorescent in the air. The platinum salt is very soluble in alcohol; this distinguishes it from amylamine, the platium salt of which is insoluble. The gold salt is also soluble.

NOTICES OF BOOKS.

The Management of Steel. By George Ede, employed at the Royal Gun Factories Department, Woolwich Arsenal. Fourth Edition, revised and enlarged. London: William Tweedie. 1866.

This is a thoroughly practical work, written by one who is intimately acquainted with the subject of which he speaks, and is not merely content with laying down rules, but gives the reasons for them, so as to make their operation clearly intelligible to his readers. It treats of the whole of the processes connected with the use of steel; its manufacture, forging, casting, annealing, tempering, and the manufacture of the various articles to which it is chiefly applied, with chapters on the case-hardening of wrought iron, and the toughening of steel for guns, railway bars, &c. The tempering of hardened steel is described at considerable length, especial attention being given to the use of oil for this purpose, which for many articles is a much more sure method of getting the correct temperature than simply observing the different changes of colour taken by the polished surface. Thus, when first the oil commences to smoke, the temper would be that of a straw colour, or about a temperature of 450° Fahr. A darker and more abundant smoke indicates a brown temper, or 500°. A purple temper, about 530°, is shown by a still more abundant and black smoke. A blue temper is reached when the oil takes fire on the application of a flame, but ceases to burn on its removal; this shows a temperature of about 580°. The usual temper for springs is shown by the oil taking fire and continuing to burn; while, if it is allowed to burn itself away before the articles are removed, it imparts the temper which clockmakers mostly use for their work, where the steel is scarcely harder than in its natural state. When a tool is required especially hard, redhot lead is recommended to heat it with, the tool itself being first raised to a dull red heat and hammered; of course, when withdrawn from the lead, it must be quenched as usual in cold water.

Many hints are given for particular descriptions of work, and some valuable advice as to selecting steel; and the popularity of the work in its present enlarged form may be safely inferred from the rapid sale of the previous edition.

Retrospect of Medicine. (July-December, 1866.) Edited by W. Braithwaite, M.D., and James Braithwaite, M.D. Lond. London: Simpkin and Co. 1867.

We always welcome Dr. Braithwaite's half-yearly volumes warmly, because they serve as an index of modern medicine, its progress, or the contrary. By comparing it with the volumes of some years back, we see with pleasure the increasing philosophical spirit leavening the science, mainly owing to the study of chemistry and physics. At the same time, we have to deplore blunders that would never have been made but from the want of chemical knowledge. We find notices of the surgical uses of liquid glass, fanciful as it may seem. A paper reprinted from the *Medical Press and Circular*, with the taking heading of Electro-Therapeutics, we were disappointed to find contained only a rather old theory of static electricity—nothing more. An interesting summary of Wagner's method of separating the sulphates of various alkaloids from broths, &c., is reprinted from the *Lancet*. But the novelty of the volume is the report of a case of poisoning by *charcoal vapour*. The reasoning for the assumption of the presence of this vapour of charcoal we find to be as follows:—"As the products of the combustion of charcoal may differ very much in consequence of variations in the supply of oxygen, it would seem that in this case the gases were either too much diluted with air to produce the ordinary effects, or that some of them (possibly carbonic oxide) may not have been formed." This cautious statement does not warrant the heading given to the case. The probably great uses of iodised cotton are shown, and a special feature of the volume is the rational treatment for the disintegration of cancer cells by the various methods of nitric and acetic acid injection, and the continuous galvanic current, as opposed to treatments for absorption or elimination. The cholera notices are not very exhaustive. We have quoted a few passages to illustrate our remarks, and we think that our readers will be enabled to verify them to a large extent by the study of the volume, which we can recommend for the purpose.

Uncontrollable Drunkenness as a Form of Mental Disorder. By Forbes Winslow, M.D., D.C.L. Oxon. London: Robert Hardwicke, 192, Piccadilly. 1866.

This pamphlet is an enlargement of three letters lately published in the *Pall-mall Gazette*. Its purport is to show the advantages to be obtained by sanatoria for oinomaniacs. It is written in popular language, and will interest all readers—we hope not too strongly, for we find two per cent. of lunacy cases caused by abuse of alcohol to be entered as suffering from *stupidité* by a foreign observer. We hope that it will prove interesting to the readers of the Chemical News generally, and in no way specially.

The Year Book of Photography, and Photographic News Almanac for 1867. Edited by G. Wharton Simpson. London: Photographic News Office.

All that we need say of the present volume is that it keeps up to the standard of the former. No very important novelty has lately appeared in photography, which has had the dulness of the summer against it, and, as a trade, has shared in the general stagnation of the year. Many valuable articles are contributed by eminent photographers on the proper management of the most approved processes, and additional information is given about Swan's Carbon Process. Altogether, we think it will be found a very fair compendium of the present state of the science.

Lectures at the School of Gunnery.—In November last a course of lectures "*On the Metals and Alloys used in the Manufacture of War Matériel*" was delivered by Mr. J. Spiller at Shoeburyness; and Mr. E. O. Brown will commence early in February next a course of four lectures "*On the Manufacture and Properties of Gunpowder and Gun-cotton.*"

CONTEMPORARY SCIENTIFIC PRESS.

[Under this heading it is intended to give the titles of all the chemical papers which are published in the principal scientific periodicals of the Continent. Articles which are merely reprints or abstracts of papers already noticed will be omitted. Abstracts of the more important papers here announced will appear in future numbers of the Chemical News.]

Sitzungsberichte der Kaiserlichen Akademie der Wissenschaften zu Wien (Mathematical and Natural History Section). Vol. 54, div. 2.

June, 1866.—"*Analysis of the Water and Gases of an Artesian Well at Vienna*," by J. Oser, F. Reim, and P. Weselsky.—"*On the Equivalents of Cobalt and Nickel*," by E. von Sommaruga.—"*On the Laws of Solution, on the Boiling of Water, and on Boiler Explosions*," by F. Pless.—"*Contributions to the Knowledge of the Hen's Egg*," by S. Stricker.—"*On the Scientific Applications of Photography and the Stereoscope*," by E. NOTICES OF PATENTS.

An Improvement in the Manufacture of Ice to fit it for making Effervescing Drinks. Oliver Weldon Jeyes, Stockton-on-Tees, Durham. March 17, 1866.

This received provisional protection only, and is described as follows:—

"My invention consists in the manufacture of ice from water or other suitable liquid impregnated with carbonic acid gas. I partly fill a vessel with the water, into which I force carbonic acid gas. I then hermetically seal the vessel, freeze the contents into a solid state, open the vessel and remove the ice, which may be employed in more or less large blocks in drinks to be made effervescing."

The fallacy of this will be at once evident to any chemist, it being well known that liquids impregnated with carbonic acid gas give it all off when frozen. However, as the specification is worded, the invention may be said to be a *bonâ-fide* one. Probably ice has never before been prepared by this method; and if a vessel of sufficient strength were used, it might be produced in this way, after which it could be "employed in more or less large blocks in drinks to be made effervescing." Doubtless the means of making the drinks effervescing will be given in a future patent. Meanwhile we should imagine that the late frost, by enabling people to procure ice in a rather simpler manner, will somewhat hinder the immediate adoption of this process.

Commercial Analyses.

To the Editor of the Chemical News.

Sir,—A letter in your last number, headed "Determination of Phosphates," bears upon a question of interest to commercial analysts. The discrepancies adverted to by the writer between the results of "high" and "low" analysts can scarcely be obviated whilst a full analysis is expected for an inadequate fee. The complete analysis of a superphosphate, especially when it contains moisture, free sulphuric acid, and organic matter, is a difficult problem, and even the most correct way of arranging the results obtained is open to doubt. It is a great pity that a general understanding cannot be arrived at to sell phosphates of all kinds by degrees (per cents.) of phosphoric acid, "soluble" and "insoluble," as is done with alkalies. This would afford sufficient information for the dealer and practical man, whilst the chemist could afford to bestow more care on this single determination.

Again, the discrepancies (possibly to the extent of several per cents.) between the results of different analysts often arise from variations in the amount of adventitious moisture, due to changes in the humidity of the air, or to the manner in which the sample was drawn, whether from the surface or interior of the bulk, and so forth. It would be extremely desirable for analysts invariably to determine the loss of weight on drying in a steam oven, which involves but little extra trouble. The results could then be stated in two columns—(A) expressing the composition of the sample as received, which would be the data for the buyer and seller; and (B) the same calculated to what it would be after drying at 212°. The latter figures would allow of a far more exact comparison being made between different analyses, as all the effect of varying humidity would be got rid of. I have occasionally sent in analyses so arranged, but, unless the practice were general, little is gained by it. A proposal from an organisation such as the Chemical Society might bring about a general agreement among chemists on such points of detail.—I am, &c.

Test for the Purity of Glue.

To the Editor of the Chemical News.

Sir,—In your last publication a good test for judging the quality of glue is asked for by a correspondent signed "J. S." There are few really good methods for accomplishing this. I have examined a large number of samples, and have tried to precipitate the gelatin, of which the glue is in great part made, by alcohol, tannin, solutions of metals, &c., but find that none of these serve the purpose for effecting a rapid determination. The best and quickest mode is to transform the nitrogen of the gelatin into ammonia by heating the glue with soda lime, and receiving the products into dilute sulphuric acid and neutralising. This is the work of a little more than one hour, and affords a very satisfactory result. Should your questioner not be practically acquainted with the estimation of material by the soda-lime process, I shall be glad, since he writes from Glasgow, to show him the method.

I am, &c. R. Carter Moffat.

Analytical Laboratory, 108, Ingram Street, Glasgow.

To the Editor of the Chemical News.

Sir,—In answer to "J. S.'s" inquiry, allow me to state the question of determining the relative value of glue has been examined and solved in an admirable paper by H. Weidenbusch. I do not recollect having seen any English translation of this paper, but it is published in *Dingler's Polytech. Journal*, vol. clii. p. 204; *Chemisches Centralblatt*, 1859, p. 434; and *Wagner's Jahresbericht der chemischen Technologie*, 1859, p. 575. The apparatus required for the determination of glue is manufactured by Mr. Desaya, the well-known philosopical instrument maker at Heidelberg. I am, &c. F. V.

Camden Square.

Amalgamation of Iron.

To the Editor of the Chemical News.

Sir,—I have read with great interest your notice of the experiments made by M. J. Nicklès in amalgamation. As I have had occasion, in making some electro-metallurgic experiments, to try if by some expedient it might be possible to amalgamate iron, I can add that iron may be, as it were, superficially amalgamated—not only by the two expedients mentioned by M. Nicklès, but also by first rubbing the iron with a piece of clean copper till it is coloured by the copper; also with tin, with common solder, and with lead. But iron takes the mercury better if slightly alloyed on the surface with tin, with an alloy of lead and tin, or with an alloy of tin, nickel, and copper, and probably with other alloys; but these are the only metals and alloys that I have tried.

Now in these cases I never thought that the iron, properly speaking, was at all amalgamated, but simply that the superposed metal was amalgamated. But M. Nicklès thinks that it is, and that it is due to electricity by means of an electro-positive metal being applied to it.

Well, zinc is certainly positive to iron in sulphuric acid and water, but ordinary brass is not; and certainly the brass of which scratch brushes are usually made is not. Very common brass is, no doubt, where the proportion of zinc is very large; but copper is negative, and lead is negative, and common solder is negative; yet with all these, when they are rubbed into the iron, amalgamation takes place equally well. Therefore, I think the result cannot be said to be an electrical one.

My notion has been, after very many experiments, that amalgamation is simply the dissolving of any metal (which is capable of being so dissolved) in mercury at ordinary temperatures. Now, I believe iron will not so dissolve, consequently is not capable on that view of amalgamation; for if, after this so-called surface amalgamation has been performed, sufficient time be given, and if there be sufficient mercury present, the whole amalgamable metal on the surface becomes dissolved, and it may be wiped off, and the iron remains just the same as it was before the operation. When the surface of the iron has been slightly alloyed with the before-mentioned alloys, this cannot be done, for the alloy penetrates the iron, and enables the mercury to do so.

That iron is not amalgamable I think may be inferred from what M. Nicklès says of it—namely, that it is not penetrated by the mercury, which it would be if amalgamation took place; though it were never so slight a film, the mercury must gradually diffuse and lose itself in the iron: a surface alloy of tin on iron does so. I have seen it stated before that iron can be amalgamated by some battery process. I should like to know the mode of operation. I am, &c.

J. Baynes Thompson.

Iodine in Mineral Phosphates.

To the Editor of the Chemical News.

Sir,—In answer to "Smatterer," I beg to state that iodine is known to be present in the phosphorite of Nassau, and it will be found upon reference to Mohr (*Geschichte der Erde*, page 514) that he cites this fact as evidence in favour of the view that this phosphorite is of marine origin.

I am, &c. F.

MISCELLANEOUS.

Composition and Quality of the Metropolitan Waters in December, 1866.—The following are the Returns of the Metropolitan Association of Medical Officers of Health:—

Names of Water Companies.	Total solid matter per gallon.	Loss by ignition.*	Oxidisable organic matter.†	Hardness.	
				Before boiling.	After boiling.
Thames Water Companies.	Grains.	Grns.	Grains.	Degs.	Degs.
Grand Junction	20·17	1·00	0·82	14·5	6·0
West Middlesex	21·00	0·90	0·64	15·0	8·0
Southwark & Vauxhall	21·08	1·98	1·82	14·5	6·0
Chelsea	19·96	1·25	0·82	14·0	6·0
Lambeth	19·83	1·49	1·34	13·5	5·5
Other Companies.					
Kent	27·38	1·10	0·00	17·0	8·5
New River	21·58	0·90	0·80	14·5	5·0
East London	23·49	1·50	1·16	15·0	5·0

The water derived from the Thames and supplied to the metropolis during the month of December has contained less saline matter than it did in the preceding month; but that derived from other sources than the Thames has contained a little less than the usual proportion. In every case, however, the quantity of organic matter has been above the average, and as it is entirely of a vegetable nature it has no doubt been derived from the decaying leaves of autumn.

The fluctuations which take place in the quality of the water during the succeeding months of the year are sufficiently marked to indicate the influence of the seasons. This may be seen from the following table, which exhibits the average composition of the water supplied to the metropolis by the Thames companies during each of the twelve months of the last two years:—

Months.	Total solid matter per gallon. Grains.	Oxidisable organic matter. Grains.
January	21·22	0·79
February	21·61	0·67
March	20·45	0·73
April	19·58	0·49
May	18·99	0·47
June	18·49	0·62
July	17·28	0·63
August	17·57	0·59
September	17·51	0·61
October	18·80	0·62
November	20·56	1·04
December	20·78	1·01

So that from October to February the total amount of solid matter in the water gradually rises to its maximum, which is rather more than 21 grains per gallon, and then it as gradually declines until at the beginning of summer it is no more than about 17 grains per gallon. Throughout the months of July, August, and September, it remains at nearly the same proportion, and then with the advance of autumn it slowly increases.

The quantity of organic matter in the water is at its maximum in November directly after the fall of autumn leaves, and its minimum is in the month of May. The same facts are observed with the water supplied by the New River and the East London Companies, whose sources of supply are very nearly of the same quality as the Thames; but it is not so with the deep chalk water of the Kent Company.

At the close of the year it may be interesting to review the results of our investigations into the character of the water supply of the metropolis during the last twelve months, and to compare it with what it was in 1851, when the last Government Commission was appointed to examine it. At that time the population of London was 2,362,236, and the quantity of water daily supplied by all the metropolitan companies was 45,885,900 gallons. This was at the rate of 19·4 gallons per head. At present the estimated population of London is 3,067,536, and the average daily supply of water is 92,734,000 gallons, which is at the rate of a little more than 30·2 gallons per head. As far, therefore, as quantity is concerned, the increase is considerable, for it is nearly 60 per cent. on the average daily supply of 1851; in fact, while the population of London has increased during the last fifteen years to the extent of only one-third, the water supply has been more than doubled. And so also with respect to the quality of the water—this likewise has undergone a marked improvement. In the year 1851, the average proportion of solid matter in the Thames supply was 21·43 grains per imperial gallon, whereas in the year which has just expired it has been only 19·64 grains. The same is the case with the water obtained from other sources than the Thames; for the amount of solid matter in the Kent water has fallen from 29·71 grains per gallon to 27·01, in the New River from 19·50 to 18·97, and in the East London from 23·51 to 20·81. But the most important improvement has been in the reduction of organic impurity. In 1851, the quantity of organic and other volatile matter

* The loss by ignition represents a variety of volatile matters, as well as organic matter, as ammoniacal salts, moisture, and the volatile constituents of nitrates and nitrites.

† The oxidisable organic matter is determined by a standard solution of permanganate of potash, the available oxygen of which is to the organic matter as 1 is to 8; and the results are controlled by the examination of the colour of the water when seen through a glass tube two feet in length and two inches in diameter.

dissipated by heat from the solid residue of the Thames supply was 2·46 grains per gallon; in 1866 it has been only 1·05 grain. In the Kent water it has declined from 2·61 grains per gallon to 1·04; in the New River water from 2·79 to 0·89; and in the East London water from 4·12 to 1·04. These facts are best illustrated by the following table:—

Comparison of the Quantity and Quality of the Water supplied to the Metropolis in 1851 and 1866.

Population	1851—	2,362,236
	1866—	3,067,536
Average daily supply	1851—	45,885,000 gals.
	1866—	92,734,100 ,,
Do., do., per head	1851—	19·4 gals.
	1866—	30·2 ,,

Companies.	Years.	Total solid matter per gal.	Organic matter, &c., lost by heat.	Hardness.	Average daily supply.

,,	1866	20·81	1·04	14·8	18,614,000

This improvement in the quality of the water has been effected in three ways—first, by selection of better sites for the collection of the water; second, by careful processes of filtration through acres of fine sand, &c.; and third, by the storage of the filtered water in covered reservoirs. Whether other improvements can still be effected is a subject for careful inquiry, and it is likewise matter for calm and deliberate investigation whether the water supply has had anything to do with the recent epidemic of cholera. On this head the Medical Officers of Health of London, and especially those who have been most engaged with the disease, will be best able to give an opinion. Already, indeed, an opinion has been expressed by the Health Officers of the Eastern districts of London, where the epidemic was most severe, and it does not accord with the popular hypothesis. H. Letheby, M.B.

The Chemical Trade in 1866.—We glean the following from Mr. W. Caudery's circular:—

Amidst the gigantic explosions which have characterised the year 1866, it is pleasing to record a satisfactory result in the chemical trade.

Alkali or Soda Ash.—No. 2 opened at 2¾d., declined about the middle of January ⅛d., but at the end of February excessive orders from the United States caused an advance of ⅜d. per cent., which was well maintained during the whole of March and April. In the middle of August 2⅝d. was accepted; 2⅝d. was paid during September and October, and 2¾d. in November and December; the present quotation being 2⅝d. ex ship. No. 1 was sold at the usual difference of ¼d. per cent. additional. Most of the Liverpool manufacturers have contracted for their full productions during the present year at prices ranging from 2½d. to 2⅝d., and as the Newcastle makers have also entered into engagements for the same period for a portion of their manufacture, the prospects are in favour of the present high prices being sustained.

Caustic Soda.—In January, 1866, the quotation was 20s. for 60 to 62 per cent., until the middle of July, when 18s. was reached, the lowest point during the year; from this it gradually advanced to 20s. 6d. at the end of September (its highest price), receding during October, November, and December to 19s. per cwt., present value.

Soda Crystals.—During the first five weeks 5*l.* 12s. 6d. was the quotation, but it advanced till the end of March, when 6*l.* 17s. 6d. was obtained. At the end of June the lowest quotation, 5*l.* 7s. 6d., was reached. Towards the end of July, an advance of 25s. per ton was at once established; from this during August to December a decline of about 20s. per ton, or 5*l.* 10s. ex ship, was submitted to, at which there are buyers for all next year, but manufacturers generally prefer waiting the chance of markets than contract, and within the last few days have advanced the rate to 5*l.* 15s. for present delivery.

Bicarbonate of Soda opened in January at 19*l.* To the end of June it gradually gave way to 16*l.* 10s., and remained so till the middle of September. 21*l.* was obtained early in November; from this it receded to present price of 18*l.*, ex ship, here.

Bleaching Powder.—During the entire year the demand has not only been extensive, but was materially increased, and although supply about kept pace with demand, high prices have ruled throughout, especially during the summer months. At the beginning of the year 14*l.* was paid, but this gave way 10s. per cwt. during January, and a further reduction of 10s. was accepted in the middle of February, when it reached 13*l.*; from this it gradually recovered until May, when 16*l.* 10s. was paid, at which, with occasional fluctuations of 10s. per ton, it remained during June, July, and August; after this consumption slackened, price declined, and 14*l.* 10s. has been the quotation since.

Tartaric Acid was quoted 1s. 6d. first of January, and 1s. 4½d. end of June; from July to December it further receded 1d., present price being 1s. 3½d.

Citric Acid met with a steady sale, 2s. 1d. being the opening, and 1s. 11½d. the closing quotations.

Oxalic Acid and Sal Acetos.—Both realised extreme rates; for the first half-year 1s. was obtained for the former, and 1s. 2d. the latter, but during the last six months they gradually gave way to 10d. and 1s. respectively. 10½d. and 1s. 0½d. may be quoted as the prices of the day.

Potash.—Bichromate sold at 6d. during the spring, but 5½d. was accepted during the last eight months of the year. *Chlorate* at the commencement of the year was quoted 1s. 2d.; present value, 1s. 0½d. *Prussiate:* Yellow from 1s. 1½d. to 1s. 0½d., the latter being the closing quotation. *Muriates:* Opening value was 9*l.* 10s., but 8*l.* was reached in September, at which it still remains.

Iodine, on January 1, was 7½d. 9¼d. was obtained in September, at which it remains.

Quicksilver.—During the first four months it was quoted at 8*l.* per bottle; at the end of April the price was reduced to 7*l.*, at which it has since remained, but with occasional sales at 6*l.* 17s. 6d.

Sulphate of Quinine.—During January prices advanced 2d. per ounce from opening quotation of 5s.; from this it gradually drooped in value till the present low quotation of 4s. 4d. was reached.

Refined Camphor.—In January it was 1s. 7d. per lb., June 1s. 6d.; during the last six weeks it reached 1s. 11d.

Cream Tartar.—In January it opened at 105s., and closed in December at 83s.

Sulphate of Copper.—The value has gradually fallen. In January it was 32s.; in December, 25s. to 26s.—present prices. The rough market also in the same way declined, best selected having been sold at 80s early in December—the lowest price known for the last 20 years; but on the 24th, same month, an advance of 5*l.* per ton was established.

Refined Borax.—Prices improved during the first month from 54s. to 60s., and remained at this latter till April, when 65s. was required. On December 17 a further advance of 5s. took place, the price being now 70s.

Ammonia.—Sulphate: Best white was 13s. 6d. in January, and 11s. 6d. in December—present value; brown and grey 10s. per ton less. *Carbonate* remained stationary at 5d. throughout the year, but the discount varied from 2½ to 10 per cent., according to quantity; the makers being behind in their deliveries, any increased demand must advance prices.

Sal Ammoniac.—The quotations for firsts and seconds continued at 37s. 6d. and 35s. 6d., with a steady demand, throughout the year.

Alum.—The opening price was 7s. 3d. for lump, and 8s. 3d. ground, but on February 14 5s. advance was obtained, making the former 7s. 6d., and the latter 8s. 6d., at which it still remains.

Sugar of Lead.—White opened at 38s., and closes at the same price; grey at 32s. in like manner; brown opened at 26s., and so continued till November, but there being a scarcity of this quality, 30s. to 32s. was required in December—present prices.

Arsenic.—Lump opened at 12s., and gradually advanced to 15s. in May, at which it remains. Powdered opened at 5s. 9d., and, in unison with lump, advanced in May to 6s. 6d.—present price.

Naphtha.—Vegetable, 4s. 3d. in January to 3s. 9d. per gallon in August, recovering to 4s. 3d. in November, at which it remains. *Mineral:* Scarcely any sale, price being nominally 2s. to 2s. 6d.

Green Copperas.—From 55s. to 65s., according to quality.

Saltpetre gradually declined in value all the year; 12,048 tons were landed, against 11,479 tons in 1865, and against 10,843 tons delivered in that year, 9812 tons were delivered in 1866. The stock now is about 10,000 tons, against 8000 tons in 1865. About 1400 tons are afloat from Calcutta, which is rather less than the quantity afloat same period last year; from Bombay scarcely any shipments are reported. Bengal petre, which was quoted at 24s. to 25s. 3d. the first week in January, has fallen step by step till last week; its highest quotation was 18s. 6d. to 20s. 6d. per cwt. Bombay is nominally quoted at 15s. to 18s. per cwt., against 19s. to 20s. 6d. in December, 1865. Refined has followed the downward tendency of raw—opening at 28s. 6d., it closes at 24s. per cwt.

Nitrate of Soda has fallen 2s. per cwt. during the year; in January the quotation was 13s. 6d., in December 11s. 6d. to 12s. The present stock is about 1200 tons, against 1900 tons last year.

Brimstone.—Prices commenced at 8*l.* 5s. for best seconds, and fell to 6*l.* 10s. towards September. In December an advance of 5s. left the closing value 6*l.* 15s. per ton. Refined roll has varied 6d. per cwt. only through the year, commencing at 10s. 6d., dropping to 10s. in September, and recovering 3d. in December, leaving present quotation 10s. 3d. per cwt. Flowers of sulphur have continued at 12s. 3d. to 13s., the former being present quotation.

Sulphuric Acid continued in active but steady demand at ¾d. to 1d. per lb., with discount varying according to circumstance.

New Chemical Toy.—"Pharaoh's serpents" and "Vesuvian tea" have paved the way for the reception of a new Chinese wonder in the shape of "ferns growing out of burning paper." This is a neat little experiment, free from many of the disadvantages appertaining both to the "Devil's tears" and the lozenge-shaped crystals of bichromate of ammonia, which may chance to prove too inviting to children's tastes. The instructions direct us to crimp or fold the yellow papers backwards and forwards, so that when opened out they may be supported upright in a zigzag form. One of these slips is then placed upright on a plate, and ignited in two or three places along the upper edge, but without being allowed to blaze. It will burn slowly down with a red glow, diffusing an agreeable perfume, whilst the ash of the paper assumes the most fantastic arborescent shapes, together with a green colour, which, to a lively imagination, may be suggestive of the growth of ferns or lichens. We had no difficulty in imitating this effect by saturating thin cartridge paper, in the first instance, with an alcoholic solution of gum benzoin, and, when dry, applying an aqueous solution of the bichromate of ammonia. The decomposition of the latter substance by heat in contact with burning paper affords an explanation of the phenomena observed.

Chemical Society.—The next meeting of the Society will be held on Thursday evening, at 8 o'clock, when the following papers will be read:—"*On the amount of Carbonic Acid in Sea-air*," by Mr. Thomas E. Thorpe. "*Synthetical Researches on Ethers*," Part II., by Professor Frankland and Mr. Duppa. "*Laboratory Contributions*," by Professor Wanklyn.

Gold by the Hundredweight. — A telegram from a friend at Placerville assures us that gold worth 50,000*l.* was taken from the Woodside quartz mine, near Georgetown, and that yesterday the miners were "blocking out nearly a pure solid mass of gold, three feet in length." If such a statement had come from a stranger we should have received it with incredulity, but we can vouch for the sincerity of the author of the message.—*Alta Californian.*

ANSWERS TO CORRESPONDENTS.

*** In publishing letters from our Correspondents we do not thereby adopt the views of the writers. Our intention to give both sides of a question will frequently oblige us to publish opinions with which we do not agree.

*** All *Editorial Communications* are to be addressed to the Editor, and *Advertisements* and *Business Communications* to the Publisher, at the Office, 1, Wine Office Court, Fleet Street, London, E.C. *Private* letters for the Editor must be so marked.

Vol. XIV. of the Chemical News, containing a copious Index, is now ready, price 11s. 6d., by post, 11s. 6d., handsomely bound in cloth, gold-lettered. The cases for binding may be obtained at our Office, price 1s. 6d. Subscribers may have their copies bound for 2s. 6d. if sent to our Office, or, if accompanied by a cloth case, for 1s. Vols. I., II., and VII. are out of print. All the others are kept in stock. Vol. XV. commenced January 4, and will be complete in 26 numbers.

J. O.—We have never heard of a substance possessing the properties you speak of. You must have been erroneously informed.

Felix.—According to Schönbein, peroxide of manganese is an antozonide.

Sydney Hall.—A large spectroscope, with the telescope replaced by a box for holding the objects to be insolated, will answer your purpose. It should be mounted equatorially, so as to point readily to the sun.

Pt.—Send your damaged crucible to Johnson and Matthey, Hatton Garden, and they will probably be able to repair it for you. The hole can be soldered up with spongey gold.

Extraction of Grease.—If CS_2 will address the undersigned, stating full particulars of his requirements, information will be afforded him as to the apparatus necessary, and where it can be obtained. Jesse Fisher, Ironbridge, Salop.

Flox.—Sulphate of lead is decidedly soluble in pure water. At 11° C. one part dissolves in 22,816 parts of water. This solution is darkened by sulphuretted hydrogen. If sulphuric acid be present, the solubility is diminished, one part then requiring 36,504 of water. The presence of ammoniacal salts still further diminishes the solubility.

Arrangement of Chemical Specimens.—A Student writes:—"It would be a boon to me, as well as, I have no doubt, to many other amateurs in chemistry, if some of your learned readers would give me a few hints as to the best plan of arranging chemical specimens. Bottles are expensive and require shelves on which to display them, and there they get dusty. Corked glass tubes are very convenient, but they are awkward for labelling, and when put away it is difficult to find a specimen. Wealthy chemists and those with whom museum space is plentiful can indulge in stoppered bottles of graduated sizes, ranged one behind another in glass cases; but such luxuries are entirely out of the reach of young beginners, whose space and pocket-money are alike limited."

Received.—T. P. Blunt, F.C.S., too late for insertion this week.

LONDON WATER: PAST, PRESENT, FUTURE.

PAST.

We propose to bring before our readers this question in an impartial manner, and to judge it upon its merits, as shown by evidence. Nor would we be so unfair as to consider the chemical evidence to the exclusion of the medical, if it be true that chemistry cannot supply the test for poison shown to be in water by its effects. As regards the past, Mr. Simon, in a report on two cholera epidemics as affected by the consumption of impure water, remarks—"An experiment has been conducted during two epidemics of cholera on 500,000 human beings. . . One half was doomed in both epidemics to drink the same fecalised matter, and illustrate its fatal results (1848-49 and 1853-54); while another section, freed, in the second epidemic, from that influence, was happily enabled to evince by a double experiment the comparative immunity which a cleanly beverage could give." To which is added in the *Lancet* report—"The population drinking dirty water suffered three and a half times more mortality than that drinking other water." At that time London was supplied by Thames water as practically as it is so now in a large measure. The classical inquiry into the state of the London water conducted by Professors Hofmann, Graham, and Miller, was made at a time about midway between these two outbreaks (1851). The results were as follow:—The percentage of nitrogen was given in two cases, in such a way as hardly to be relied upon, "and on such evidence a minute and probably unimportant portion of *animal* organic matter would be admitted to be present;" none had any marked taste or colour; no animalcules were observed in any case, with the statement that the time of year was unfavourable to such observation. The hardness of the water was shown to be temporary and permanent in character (sixteen degrees of hardness from sulphate of lime in the Kent water), and this hardness was shown to be "remarkably uniform."

It may safely be stated that no sufficient grounds exist for believing that the mineral contents of the water supplied to London are injurious to health. The water may be circulated through leaden pipes with an unusual degree of safety from this hardness, and iron is protected by the alkaline character of the salts in the water. Putrefactive decomposition occurs less rapidly in hard than in soft water, and it may be more safely preserved in reservoirs on this account. The supply is *limitless* (although the Thames is fed by no great lake), and this is nearly independent of the season, on account of the water by which the Thames is fed being from a chalk soil.

The water was reported as being defective as regards temperature (sometimes above 70° F.); promoting decomposition of organic matter; taste of vegetable matter after floods; and vegetable discolorations, "which do not originate on a barren non-retentive soil—an evil to be obviated by a restricted area—with storage of excess from floods in large reservoirs." Pollution by sewage and surface drainage ("the diverting the sewage of the various towns entirely from the Thames need not be taken into account, from the great difficulties in the way"), *for the indefinite dilution of such matter in the vast volume of the well-aerated stream is likely to lead to their destruction by oxidation.* However, the evil is shown to be likely to increase, and "it seems to be only a question of time when the sense of violation of the river's purity will decide the public mind to the entire abandonment of the Thames as a source of supply, unless artificial means of purification be in the meantime devised and applied. This very significant passage we also find in the Report. "Although, according to chemical analysis, the organic matter never appears to rise in the water of the companies who filter, to a proportion by weight which need elude the chemist, and although it may be impossible to ascertain its origin, still the balance of evidence appears adverse to the conclusion *that what is known to enter is immediately destroyed.*" Thus the hardness of the water is useful only for the carrying away of the matter, not for preserving this organic matter to putrefy in the human body. Refuse from gas and chemical works, not admissible in ordinary sewers, and navigation, and river population also, now pollute the river. The disadvantages of hard water are shown fully, and it is useful to compare these statements with that of Mr. Bateman, who says that the Glasgow water in London would save no less than 400,000*l.* per annum in the use of soap, soda, tea, coffee, and chemical substances.

Filtration was shown to be absolutely necessary to the purification of the water, sand filtering being insufficient, clay and loam (suggested by Professor Way's researches) inapplicable, whilst liming reduced the hardness in one case from 15·5 to 3·6 degrees of hardness (Clarke's method) the process falling in easily with "the routine operations of waterworks." Water so treated "could not be distinguished in its sensible properties from pure spring water of equal softness." This process would not supersede the necessity for sand filtration. The two processes combined could not remove the yellow-flood tinge, or abate the taste of vegetable matter.

At this time a scheme was proposed for obtaining water from the district near Farnham, of an area of thirty-five square miles. The supply was shown to be over-estimated. In another part of the Report the difficulties in the way of a soft-water supply are discussed,—1st. The question of storage and putrefaction, which might be overcome. 2nd. Discoloration from iron pipes. 3rd. Danger of lead solution. But it is noted that at Glasgow lead-pipes and cisterns are used with a constant supply "without any *apprehension* of lead poisoning." Sulphates did not seem to protect from lead solution, chlorides favoured it, carbonate of lime seemed very protective, and carbonic acid even more so. One-57th of a grain of lead per gallon only was left by exposure of water, which contained six grains of the oxide, to the air for twenty-four hours. Pure water became highly poisonous; with carbonic acid in solution the water

remained safe. Organic matter in soft water is doubly dangerous. Dr. Smith, of Aberdeen, considered less than $\frac{1}{20}$th gr. of lead harmless; minimum evil results follow from between $\frac{1}{10}$th to $\frac{1}{20}$th gr. per gallon; but mostly when soft water was used with the consequent ill effects, leaden *cisterns* were not used. In conclusion, these gentlemen enumerate as the properties to be preferred in the water for the supply of the metropolis—1st. Freedom from putrescible organic matter. 2nd. Freedom from discoloration, constant or not. 3rd. Softness and coolness; for these reasons the chalk strata supplies were recommended, as being inexhaustible with all recommendations except the third, which, being temporary, may be removed, "and the superiority of the spring over the river water is most apparent."

We propose treating of these matters as concerns the present and future—showing what has been done, and what remains to be done, whether any of these statements now apply, and what additional reasons and remedies bear now on the question.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

Note on the Crystallisation of Glycerin, by William Crookes, *F.R.S.*

My attention has been drawn by my friend Dr. W. S. Squire, of the firm of Burgoyne, Burbidges and Squire, Coleman Street, to the hitherto unobserved fact of the crystallisation of large masses of glycerin during the recent cold weather.

About five tons of glycerin, in casks of eight cwt. each, were recently imported by this firm from Germany. When they left the factory the contents were in their usual state of viscid fluidity; but, on arriving in London, they were found to have solidified to a solid mass of crystals, so hard that it required a hammer and chisel to break it up.

A large block of this solid glycerin, weighing several hundredweight, suspended in a somewhat warm room, took two or three days to liquify, and a thermometer inserted in the fusing mass indicated a constant temperature of 45° F. In small quantities the crystals rapidly fuse when the bottle containing them is placed in warm water. The original glycerin was pale brown; the crystals formed from it are nearly white, whilst the liquid which drains away from it is dark brown. In quantity, the solid glycerin looks very like a mass of sugar candy. The isolated crystals are sometimes as large as a small pea; they are brilliant, and highly refracting, when rubbed between the fingers they are very hard, and they grate between the teeth. Their form appears to be octahedral, but this is difficult to ascertain accurately, owing to the viscidity of the mother liquor which adheres to them.

The crystals, separated as much as possible from the mother liquor, and then fused by heat, form a clear and nearly colourless liquid, slightly more viscid than usual, which, as far as I have been able to ascertain, possesses all the physical and chemical properties of pure glycerin. It is perfectly miscible with water and alcohol. It has been especially tested for sugar and glucose (common adulterants) with negative results; lead is also absent, and nitrate of silver only produces slight turbidity in its aqueous solution. I believe it to be almost chemically pure anhydrous glycerin.

Some of the fused crystals have been exposed for several hours to a temperature of 0° F. without solidification taking place. The only result was that the liquid became more viscid.

The cause of the crystallisation is not very clear. The most probable explanation is that the vibration of the railway journey across Germany, added to the intense cold to which the glycerin was simultaneously subjected, enabled the particles to arrange themselves in a regular form. The phenomenon then becomes analogous to the crystallisation of wrought iron under the influence of vibration, the gradual solidification of syrupy solutions of organic alkaloids, and the familiar crystallisation of refractory platinum salts in a watch-glass by judicious friction with a stirring rod. Experiments are about to be tried to see if the crystallisation of glycerin can be determined by exposing it to a low temperature, and at the same time setting the particles in a state of vibration.

Should the above view of the cause of this curious phenomenon be correct, we may imagine that, during the railway transit, the vibratory movement was determining at the same time the crystallisation of the glycerin and the railway axles, the rapidity of the action being in the inverse ratio of the viscidity of the two bodies.

On the Preparation of Pure Silver, by Professor* J. S. Stas.

I have had recourse to two distinct methods to procure the pure silver necessary for the different purposes treated of in my investigations.

First Method.—To carry out the first method, I dissolved at the boiling point 3500 grammes of French silver coin in very dilute nitric acid. The nitrate of silver produced, after having been evaporated to dryness and fused, was kept at its point of fusion as long as oxygen compounds of nitrogen were given off. The nitrate mixed with nitrite was dissolved when cool in the smallest possible quantity of cold water, and the solution, after resting forty-eight hours, was filtered through a double filter to separate all the matter that might have remained in suspension. The limpid solution, diluted with thirty times its volume of filtered rain-water, was precipitated by an excess of pure hydrochloric acid. The chloride of silver formed was, when deposited, washed by decantation, first with water acidulated by hydrochloric acid, and then with pure water. This washing was performed by shaking the chloride violently each time in large stoppered bottles with the necessary quantity of liquid.

It was then spread upon a cloth that had been washed with hydrochloric acid, strongly compressed, and left to dry spontaneously. When perfectly dry it was finely powdered and digested for several days in aqua regia. It was then again washed in distilled water.

As the reduction by heat of chloride of silver with carbonate of sodium is a most delicate operation when performed upon large quantities, I made this reduction at a low temperature under the influence of a solution of caustic potash and sugar of milk, as first proposed by Levol.

To procure potash and sugar of milk free from heavy metals, I added to a concentrated solution of hydrate of potassium, previously boiled, a slight excess of a solution

* Abstract from *Memoirs of the Royal Belgian Academy.*

of sulphhydrate of potassium to precipitate traces of dissolved metals. After the deposit of the metallic sulphides, I decanted the alkaline solution and put it in contact with freshly precipitated oxide of silver to deprive it of the sulphhydrate of potassium. After a sufficient digestion and rest, I separated the excess of oxide of silver and the sulphide of silver that had been produced.

By the same means I eliminated the heavy metals contained in an aqueous solution of sugar of milk.

The chloride of silver, distributed in three large porcelain jars, was digested at a temperature of from 70° to 80° C., with the mixture of solutions of hydrate of potassium and sugar of milk, until all the chlorine was separated from the silver. The metallic silver, which was grey, was washed with water until the excess of alkali had disappeared, then digested with dilute pure sulphuric acid, and lastly washed with ammoniacal water. After being dried, 5 per cent. of its weight of calcined borax was added, containing 10 per cent. of nitrate of sodium, and then, with the necessary precautions, it was fused in a "Paris crucible."

The fused metal was then poured into a mould coated with a paste of mixed calcined and non-calcined kaolin. The bars of silver, first cleaned with sharp sand, were then heated to redness with caustic potash from tartar; the adhering kaolin having been dissolved, the bars were washed in pure water.

They were divided into small blocks by means of a chisel of tempered steel. As the hardest chisel leaves traces of iron on the surface of the silver, the small blocks were digested with warm hydrochloric acid, pure and concentrated. The silver was then washed with ammoniacal water, and lastly with water, and heated up to its fusing point before being placed into a well stoppered bottle.

I procured, *at a single casting*, 2875 grammes of silver of an extraordinary whiteness.

I will subsequently state how I assured myself of its state of purity; I wish first to describe the second method which I made use of to procure large quantities of pure silver.

(To be continued.)

On the Nature of the Gas which is given off from Fresh Charcoal when immersed in Water, by William Skey, *Analyst to the Geological Survey, New Zealand.*

(*Concluded from page* 15.)

In contemplating the results of these experiments, the first and most striking circumstance claiming our attention is that charcoal which has already yielded its proper quantity of nitrogen to water can be made to yield quite as much by reigniting it in air and renewing its contact with water; and these processes can be repeated with like effect so long as there is any charcoal remaining. From this, then, it would appear the gas is not derived from the charcoal in the first instance, but from the air. This view receives complete confirmation from the result of the ignition of charcoal in salt; for in this case, air being excluded from the incandescent charcoal, there was no evolution of gas when it was placed in contact with water. It is therefore certain that charcoal has the capacity of retaining nitrogen gas to itself in certain quantities at high as well as at low temperatures, as De Saussure has shown.

Leaving, for the present, the discussion of the manner in which nitrogen is retained by the charcoal, it is next seen that, as with gases absorbed by charcoal at low or ordinary temperatures, the gas which has attached itself to charcoal at high temperatures is also wholly or partly liberated by water, by which, indeed, alone the fact of its retention could well be discovered.

Now, the only other simple liquid which as yet I have found to have this effect upon charcoal is bisulphide of carbon. The oils have no such effect. The capability of such fluids as alcohol, ether, &c., to cause the evolution of gas described is no doubt due to the water they severally contain.

But by a reference to the experiments with concentrated sulphuric acid and solution of hydrate of potash and chloride of calcium, it will be seen that even water has not always these effects upon charcoal. When held in the bonds of powerful affinities it utterly fails to produce them.

The liberation of the gas retained at high temperature by charcoal being thus only effected by certain liquids would appear to show most conclusively that such liberation of gas is not due to a mere mechanical displacement of the gas by the water, but rather that it is due to the exercise of chemical forces.

What part the water or the bisulphide of carbon really plays in these effects they produce, however, does not yet appear. Whether, as substitute for the gas evolved, they are transferred bodily to the charcoal without decomposition, or as an effect of selective affinity, or whether they are decomposed and their constituents combined separately with different portions of the charcoal—which of these reactions, if either, really obtain, is difficult to determine. But taking the case of water, and considering the limited amount of combustible gases supplied to the interior of the charcoal during ignition, the last supposition appears the most probable, since under these circumstances it is almost certain that compounds have been formed of the elements of the ignited mass, which possess such powerful and unsatisfied affinities for oxygen and hydrogen that their sum is equal to what is required for the decomposition of a portion of the water employed.

The manner in which this gas is retained to the charcoal now remains to be considered.

In the first place, it may be retained mechanically or chemically; that it is the latter appears the most probable, since, according to De Saussure, gases absorbed to charcoal by "mechanical absorption are expelled by the accession of heat."

Assuming, then, it to be retained to the charcoal in obedience to chemical affinities, we have finally to consider what is the composition of the chemical compound which the nitrogen gas contributes to form.

Two views of the composition of this hypothetical body here suggest themselves, one of which is, that it is a simple binary compound of the nitrogen with the carbon of the charcoal; the other, that it is a complex compound of nitrogen with two or more of the constituents of the charcoal, one of which is carbon.

From a hasty view, the first of these views might appear the nearest the truth, but I would submit that to adjudge these questions properly requires an enlargement of our knowledge respecting the real nature of charcoal itself.

With regard, indeed, to its chemical composition, this is pretty well known, but this knowledge we have hardly used to its legitimate purpose. Thus, though well aware how pertinaciously the gases oxygen, hydrogen, and nitrogen cling to charcoal, we are in the habit of using

the word "charcoal" as a mere synonym for impure carbon, when it is obvious that at least a portion of the carbon of the charcoal must be in chemical combination with these gases, since we know of no combination among oxygen, hydrogen, and nitrogen of such permanence as to be capable of resisting a degree of temperature approaching to that at which charcoal is made.

Thus leaving the earthy salts present in the charcoal out of the question, we are constrained to admit of the presence of a carbonaceous compound in what is considered a variety of impure carbon; but the question here arises, if a portion of the carbon is thus taken up by these gases, why may not the whole of it, since there must be a most intimate mixture of these several elements with each other, and beside a tendency among the residual constituents of the organic matters operated upon, to arrange themselves in the most permanent forms, and this will of course be the most surely effected by employing the whole of the carbon in this manner.

If this view is correct, it will follow that what is so often referred to as an allotropic variety of carbon is in reality a carbonaceous compound, or more probably a series of such, there being not a particle of free carbon present in it, and therefore the question raised as to whether the nitrogen retained to it at a high temperature is combined with carbon alone or with carbon and one or more elements in addition, receives an answer in favour of the latter hypothesis. It only remains then now to briefly consider what is the probable nature of this complex compound here supposed to exist.

Now, one of the known effects of heat upon organic substances of the nature of wood-coal is to remould their elements, or a portion of their several elements, into acid, basic, or neutral volatile compounds; these latter greatly predominate; but, with very good reason, they are generally supposed to be compounded of the two former, and they are therefore viewed as resolvable bodies.

If, then, those portions which are capable of being volatilised have such a tendency to combine together in certain definite chemical forms we call acid and basic, why may not the fixed or residual portions have similar tendencies equally with the former? The elements of this residual portion have been liberated from combinations built up, under the influence of vital force, to reunite themselves, as has been shown, in chemical union; and, what is more likely than that, with a regard to those general laws which regulate the combination of the elements with each other, they should seek to arrange themselves under each of the two great natural divisions which these laws are constantly striving to enforce, so as to present us with a compound or compounds consisting of both acid and basic substances—in exact equipoise, to form a neutral salt or a series of neutral salts, designated collectively under the unscientific and ill-fitting appellative, charcoal?

The distinguishing feature between these hypothetical bodies would most probably be the presence of nitrogen in those of them playing the parts of bases, and in those only; while a maximum proportion of the oxygen present would be found in those portions possessed of the opposite characters.

The whole of the nitrogen, therefore, present in the charcoal, that originally existing in the wood whence the charcoal is derived as an organic compound, and that absorbed by the charcoal from the air under the influence of heat, I would assume to exist as a constituent portion of these basic compounds; but with this difference, that while the nitrogen derived from the wood itself helps to form a stable compound in presence of water, the nitrogen chemically absorbed from the air is employed to form a very unstable one in presence of the same liquid.

In conclusion, it should be stated that the capacity of charcoal to absorb weak acids and bases, and certain so-called neutral substances, would seem to support to no small extent the views of the constitution of this body here advocated; while, at the same time, the necessity for assuming such a force as mechanical absorption to account for this phenomena (of absorption) is removed, if such a constitution of charcoal is once admitted in theory; for it is almost certain that if charcoal indeed is a mixture of carbonaceous salts, either portion thereof, the acid or basic, will be as insoluble in water as the combination of the two. And because of this insolubility their affinities will be feeble even for each other; it follows, therefore, when other substances are presented thereto, possessing superior basic or acid properties, and free to act, they attach themselves by chemical force unto a portion or the whole of the carbonaceous acids or bases of which the charcoal presumedly consists. To form compounds partaking of the insolubility of these carbonaceous portions, and where these are not volatile, therefore they can only be removed from the charcoal by the application of others possessed of more powerful affinities for them than is exercised by the carbonaceous portion of the new salt.

Indeed, the arguments in favour of admitting a constitution to charcoal such as is here advocated, should properly have been made to rest for their chief support upon its behaviour to weak acids and bases in aqueous solutions; but to avoid going an undue length, I have chosen the present course, although the material for it is all brought together. In case, however, these views receive any favour, I shall make use of it in a further communication.

It has been more lately ascertained that the coke of lignite, or brown coal, when cooled down from a red heat under mercury, yields about one quarter more of nitrogen gas for the same volume than wood charcoal under similar circumstances; the coke of non-hydrous or bituminous coal yields considerably less; while, in the case of recently-ignited bone-charcoal, graphite, the yield of gas to water is at a minimum, though still it is sufficient to enable us to test the amount.

FOREIGN SCIENCE.

(From our own Correspondent.)

Paris, January 15, 1867.

M. Ch. Mene, gold medallist of the Imperial Society of Sciences, Agriculture, and Useful Arts of Lille, has written a memoir on analyses of cheese. The method consists in ascertaining the density of the cheese, and discovering if there be any reaction—acid, alkaline, or neutral. He then finds, by desiccation, the weight of the water it contains, the proportion of casein, the fatty matters, and determines the different fatty acids which compose them. If there are other organic acids present, he seeks to find out their nature and proportions. Lastly, incineration gives him the weight of the ashes, the mineral salts which the cheese contains, and he terminates the analysis by determining the nature and weight of the acids and bases which form these salts. I forgot to say that, by a special determination of the proportions, he finds the weight of the nitrogen in the cheese. This is an important element of the analysis. If this long series of analyses were to be resumed in a few words, we would say that quantities of water are found in cheeses varying from 20 per cent., which the Parmesan and Roquefort contain, up

to 78 per cent., which correspond to fresh cheeses. The Marolles and Poitiers cheeses have nearly the half of their weight of casein. It is almost totally absent from the cream sold in Paris under the name of cheese. The fatty matters of butter are abundant in these latter. Dutch cheese contains 35 per cent., and white cheese 8 per cent. of casein.

It is the dry cheeses—the Dutch, the Parmesan, &c.—which contain the greatest relative proportion of ashes; the fresh cheeses give less. If we would seek to know what gives so marked a taste and odour to certain cheeses, it will be found that it is occasioned by the butyric, lactic, and valerianic acids united to the ammoniacal salts.

Aliments rich in nitrogen are considered as possessing nutritive qualities in the highest degree; and far before bread or meat, we find the Dutch, Gruyère, and Roquefort cheeses. They contain from 26 to 40 per cent. of nitrogenised matters; meat only contains 22 per cent. Of course, if we consider the aliments from a respiratory point of view, cheese can only introduce combustible elements into the body by means of the fatty matters it contains. In this property it yields only to butter and fatty substances properly so called. If mineral substances be the object sought, we must again have recourse to cheese, which contains 7 to 8 per cent. of ashes, whereas meat and bread only contain 1 per cent. A last term of comparison remains—viz., the flavour and the aroma, its exciting properties. But here chemical analysis is of no use whatever; no one contests these qualities inherent in cheese. On this point we may invoke the unanimous consent, not of numbers, but of all *gastronomes*.

After a great number of fruitless trials to ascertain the proportion of nitrogen in commercial organic matters, such as manures, with recipients filled with soda-lime, M. Mène came to the determination of employing earthenware retorts, analogous to those with which oxygen is obtained from the peroxide of manganese heated to a dull red. He fills them with fragments of caustic potash, in the midst of which he introduces the matter imbued with caustic soda, and formed into balls. He then heats them by commencing the fire at the top. To the tube of the retort he places an apparatus of glass, plunging into diluted hydrochloric acid, so as to absorb the ammoniacal gas, which is evolved by the reaction of the potash on the organic matter. The temperature may be raised to an incipient cherry-red without fear of seeing the retort melt by the action of the potash, and the organic matter is then perfectly destroyed. There is no fear of the destruction of the nitrogenised matters by the action exerted by the potash to convert them into ammoniacal gas,* for direct experiments on special matters, such as albumen, casein, &c., have given in nitrogen exactly (or rather *more* than *less*) the numbers indicated by certain authors, and consequently there can be no doubt on this ground. The determination of the nitrogen, with this modification of the ordinary apparatus, is obtained by the process of Messrs. Will and Varrentrapp—that is, by precipitating the ammoniacal salt by chloride of platinum and calcining it, so as to obtain the weight of the platinum, from which the nitrogen is calculated. By the aid of the modifications which he here indicates in order to obtain the proportion of nitrogen in commercial products, such as manures—that is to say, operating on a large quantity of matter—he here remarks that many figures admitted for certain products as holders of nitrogen should certainly be corrected.

M. Fremy has just published, through Gauthier-Villars, a small pamphlet in quarto, which in the highest degree deserves the attention of the public. We refrain from reproducing any of it, so as not to injure its sale (the price is 50 centimes, or 5d.), made for the profit of the Society of the Friends of Science; but we announce the aim of M. Fremy. He asks the creation of *sixty places*, to be given to persons who cultivate with most distinction the mathematical, physical, and natural sciences, with the mission of advancing science by their labours. They would be divided into three classes, with salaries of 80*l*., 160*l*., and 240*l*. When, in a few months' time, strangers, attracted towards us by the Exhibition, come to tell us of their magnificent laboratories, which, as those of Germany, have often cost several millions of francs, we can say to them, France has better still; she possesses an admirable institution, the aim of which is to provide for all those who follow a scientific career with success.

We are glad to hear that M. H. Schmidt-Missler's products of the pine tree, forest wool and other substances, are at present in active industrial development in Paris. Let us enumerate them rapidly. *Vegetable Wadding:* This preparation preserves all the properties of the pine; it evolves an aroma eminently wholesome. Dr. Schillbach recommends it as a most harmless, but efficacious remedy in cases of catarrh, bronchitis, asthma, sore throat, &c., &c. *Raw Vegetable Wool:* One-half cheaper than the ordinary wool mattrasses. Those stuffed with this wool do not attract humidity; its odour and the ozone due to its resinous principles keep off or kill the insects. *Schmidt-Missler Flannel.*—By reason of the resin, the tannin, and the formic acid it contains, it aids the exercise of the important functions of respiration, absorption, and perspiration, in a greater degree than ordinary flannel. It is at the same time a preservative and corrective agent which merits to become popular in Europe as it is in Germany, and can be woven into any of the forms for which flannel is used, such as mittens, waistcoats, drawers, socks, &c. *Etherated Pine Oil.*—Employed in friction, it has given unexpected results; in the first commencement of paralysis and apoplexy, in the case of recent burns, &c. Some German doctors recommend a few drops in sugar and water to be administered internally as a remedy against cramps in the stomach, worms in children, neuralgia, dropsy, &c. There are also the *Solid Extract of Leaves of the Maritime Pine, the Pine Spirit, and Pine Soap.* All these different products are a most simple but very valuable acquisition. In the *Cosmos* of August 15, 1852, we had called attention to the first of the two establishments founded in Silesia, in the Prairie de Humboldt, by an ancient inspector of forests, M. Pannewitz, for obtaining various products, similar to those above enumerated, from the leaves of the pine tree.

A meteorite fell at Kniahynia, comitat of Unghvar (Hungary), from a perfectly serene sky, on June 9, 1866, between four and five o'clock in the afternoon. A violent detonation similar to that which would be produced by the simultaneous discharge of a hundred cannons, accompanied its appearance, which took place under the form of a grey cloud ten times as large as the apparent disc of the sun, and uniting on all sides columns of greyish smoke, without any vestige of luminous appearance. Two or three minutes afterwards a noise was heard like that of a multitude of stones rattling together and lasting ten or fifteen minutes; after that the fall of stones took place. Several eye witnesses at localities six to twelve Austrian miles (the mile = 7½ kilometres), and especially those to the west of Epuriès (twelve miles to the west of the point where the fall took place), describe the meteor as having presented the appearance of a yellow and orange luminous globe, followed by a train bordered with ultramarine blue. About sixty stones were picked up; they were of the general structure of bodies of this class, and covered, as usual, with a coating of black enamel. The heaviest weighed 550 lbs.; it was broken in two by the violence of the shock, and fell in a field, where it penetrated the earth to the depth of eleven feet (Viennese), leaving a hole more than four feet in diameter. Their density at 20° R. is 3·520. They were quite hot when first obtained, and kept their heat for hours, some for days.

Mr. Toselli, 236, Faubourg Saint-Martin, has made a

* It is well understood that oxygenatod nitro-compounds cannot be analysed for nitrogen by this process.

new ice-making machine on wheels. When Mr. Toselli produced, in 1862, his Italian ice-making apparatus which acts by the cold produced by the mixture of two deliquescent salts, two kilogrammes of salt were obliged to be employed, at the cost of 2 fr., in order to obtain on an average 300 grammes of ice; so that when the idea was given up of recrystallising the salt by evaporation, the kilogramme of artificial ice cost 25 fr. Substituting for the salts employed up to that period a mixture composed of one part water, one of sub-carbonate of soda, and one of nitrate of ammonia, salts which he sold at 1 fr. the kilogramme, and which by their solution produced a cold of 29° C. below zero, Mr. Toselli reduced the cost of artificial ice from 25 fr. to 2 fr. 50 c.; and his small ice-making machines enable us to obtain without difficulty, at a cost of less than 1 fr., 400 grammes of ice very pure and clear, or iced sherbets for five or six persons. The success of this machine and the salts was so great that, in 1864, he sold 20 tons of salts, and in 1866, a cold and damp year, nearly the same quantity. He made, at the commencement of this year, a curious and important observation which opened a new field for him. If, instead of adding to the water at the same time the carbonate of soda and the nitrate of ammonia, the dissolving of which produces a cold of 29° C., the subcarbonate of soda alone is first dissolved in the water, then, ten or twenty minutes afterwards, the nitrate of ammonia is added, the cold produced descends to 34° C. below zero—*i.e.*, more intense by 5°—a very considerable difference, which physicists must account for. This theoretical discovery soon afterwards became a practical one; for this method of operating, the previous dissolving of the salt of soda, has enabled the inventor to substitute for the nitrate of ammonia—a salt rather rare and dear—another salt, more common, which gives, however, a cold of 28° below zero, and enables him to obtain ice, at once, wherever the temperature of the water does not exceed 25° C.

At present Mr. Toselli has for sale, all prepared and put in a box, for the price of 50 centimes (5d.), a new refrigerating mixture, which gives the same quantity of ice as the former mixtures costing 8 fr. This is, as may well be seen, an immense progress in the production of an object of almost prime necessity. After having lowered in such an enormous proportion the prices of the substances producing the cold, it became necessary to simplify the instrument or ice-making machine; thus, the last model made by M. Toselli, called by him the "*glacier roulante*," has exceeded all expectations. It is a simple metallic cylinder mounted on a foot. The salt of soda and the salt of ammonia are added in two operations, as we have before stated, the smaller cylinder containing the water to be frozen is introduced into the interior, and the orifice is closed by an indiarubber disc, and then by a cover fastened with a catch; the cylinder is then placed in a sac, or case of cloth, and it is made to roll on the table with a slight oscillatory movement given by the hand. After a lapse of ten minutes the water in the interior of the cylinder becomes a beautiful cylinder of ice. Nothing is more simple, more economical, or more efficacious than the new "*glacier roulante*," which costs 10 fr., and gives us, moreover, what could not hitherto be obtained with an apparatus containing freezing mixtures—the means of freezing a decanter of water or a bottle of champagne. The apparatus in a case, packed for travelling, with 20 kilogrammes of refrigerating materials and a measure, costs, at present, only 1*l.* It is incredibly cheap.

F. Moigno.

A Chemist in Trouble.—We read in Monday's *Times* that "a lecturer on chemistry, botany, and other branches of natural philosophy," was arrested as a Fenian at Portland Row, Dublin, on the 12th inst.

PROCEEDINGS OF SOCIETIES.

MANCHESTER LITERARY AND PHILOSOPHICAL SOCIETY.

Ordinary Meeting, December 26, 1866.

Edward Schunck, *Ph.D., F.R.S., President, in the Chair.*

Mr. Peter Hart exhibited a piece of lead pipe from the Ardwick Bridge Chemical Works, coated internally with oxide of manganese. The pipe was one inch in diameter, and the thickness of the coating of oxide of manganese was about a quarter of an inch. The oxide has not been minutely examined, but it consists no doubt largely if not wholly of the hydrated peroxide, as it evolves chlorine in quantity when gently heated with hydrochloric acid. The water used in the works is collected in tunnels cut in the red sandstone, and there is no doubt that the source of the manganese is the refuse chloride from the chlorine stills situated almost immediately over one of the tunnels. A portion of this chloride, having filtered through the sandstone, has come into contact with the bicarbonate of lime in the water, chloride of calcium and carbonate of manganese have resulted, which latter body, by after contact with oxygen, has become wholly or partially converted into peroxide.

"On some recent observations on the Specific Gravity of Sea Water," by Thomas Heelis, F.R.A.S.

The author had in the course of several long voyages accumulated a number of observations on this subject, all of which were made at sea with the hydrometer. On coming to examine and reduce his results, he had referred to a paper by the late Professor Forchammer, of Copenhagen, published in the Philosophical Transactions. The results arrived at by the Professor differed so much from those obtained by the author that a careful examination of the Professor's paper became necessary before any progress could be made in the reduction of the author's observations, as, if the results of the Professor were correct, the observations must involve such errors that their reduction would be useless. The examination was therefore undertaken, and was extended to the results of the American observations, which are shown in a curve given among the plates to Maury's Physical Geography of the Sea (ninth edition). The American observations were found to accord with those of the author and to differ from the results obtained by the Professor to an extent in some cases of one per cent. of the total salinity. The apparent cause of the discrepancy seemed to be the length of time during which some of the Professor's specimens were kept before being subjected to analysis, the paper in the Philosophical Transactions showing that in one case at least this interval amounted to some twenty years. A further examination of the paper showed, as the author conceived, great errors in arrangement, and especially in the determination of the areas, all the water taken in which was assumed to be from the same region, and all the results of which specimens were included in a common average. There was a strange deficiency in the observations for certain regions, but the boundary lines of the areas were so arranged that the Gulf Stream was included in three regions, the L'Agulhas current in two, and the Equatorial current in two at least; so that if the results had not been drawn from too few specimens, the effect of the high specific gravity of these currents would have been entirely masked by the observations of other water not the subject of current, but included in the averages as belonging to the same regions. As it was, the same result—viz., the disappearance of the effect on the average of each region of the high specific gravity of the waters of these currents was found to occur because of the small number of observations in the currents, there being only one, for instance, of the L'Agulhas current, and this one being masked in the average of the Indian Ocean region,

the specific gravity of part of which, as is well known, is reduced by the fresh water of the large Asiatic rivers.

PHOTOGRAPHICAL SECTION.

December 13, 1866.

J. BARNDELL, *F.R.A.S., Vice-President of the Section, in the Chair.*

Mr. COOTE exhibited a frame for printing transparencies on glass, of which the following is a description :—

As frames for printing transparencies for the lantern and stereoscope have occupied some little attention of late, in the *British Journal of Photography*, I thought it might be useful to submit to the inspection of the meeting to-night one that I had made last winter for printing stereo-transparencies from negatives, on plates 7¼ in. by 4½ in., the size I always use on account of being able to take single pictures in the same camera. The frame is the same in principle as the usual frame for printing transparencies by superposition, and without having to cut either negative or print by simply moving the prepared plate and negative to the right and left in opposite directions alternately; but it is a little longer, and 4¼ in. broad inside. The opening for exposure is in the centre, but is made longer than is required for a stereo print. Over this opening I place a mat made of thin brass, the desired size and shape of the picture required. This mat is sunk into the bed of the frame until it is quite level with it. A negative is then put in, and by moving the mat up or down in its recessed bed, you can get more sky or foreground at will, and the movement right and left gives you any other portion of the picture you may desire. Having settled that point, I then place on the negative a *straight* strip of soft cardboard, wide enough to reach, within about an eighth of an inch, the bottom of the opening in the mat; and then place on the prepared plate, which is kept in a horizontal position by resting on the strip of cardboard; and it also enables you to get the two sides of the picture exactly on a level with each other after reversing, to close the frame. A loose back, with a brass spring on, is put in, and a small lever bar brought down over the spring and held in its position by a small catch. It is necessary to have several strips of cardboard, varying in width, and it will be obvious to any one that they must not exceed in thickness the glass of the prepared plates, otherwise the pressure of the back is kept off the glass and the plates are not in close contact.

By use of this frame I can easily take out for the lantern portions of pictures taken the full size of the plate, say 7¼ in. by 4¼ in., whether the subjects be horizontal or upright.

Mr. DANCER then exhibited, by means of the oxy-hydrogen lantern, a very beautiful series of views by Mr. Buxton, representing scenes in Scotland, Egypt, India, &c., and also views in Derbyshire, Cheshire, and other places, by Mr. Coote and Mr. Brothers.

ACADEMY OF SCIENCES.

December 24, 1866.

"*On the Inverse Consecutive Changes of Volume attending the Formation of Ammoniacal and Alkaline Salts in Water*," by M. J. Regnault.

"*On the Absorption of Hydrogen and Carbonic Oxide by Melted Copper*," by M. Caron. Copper of good quality, weighing about 200 grains, is melted in a boat in a porcelain tube, and hydrogen passed over it, the apparatus being so arranged that the copper could be seen during the whole operation. As soon as the metal fused, it appeared to intumesce, and water was condensed on the cool part of the apparatus. When the oxide which the copper contains is completely reduced, the surface of the metal is as brilliant and mobile as that of mercury. On cooling, a little before solidification, the mirror-like surface becomes agitated and appears to boil up, the escaping gas projecting a multitude of fine drops of copper. The metal then swells, and the solidification terminates by a final incomplete eruption. The ingot of metal, after cooling, is found to be porous. Exactly the same phenomena takes place when the hydrogen is replaced by carbonic oxide.

"*On Protoxide of Nitrogen as an Anæsthetic Agent*," by M. Preterre.

December 31, 1866.

"*On Vital Resistance*," by M. F. A. Pouchet.

"*On the same subject*," by M. Pasteur. These two notes contain additional arguments on the subject of spontaneous generation.

"*On the Argentous and Argentic Hydrates*," by M. P. Weltzien. When a plate of very clean silver is introduced into a neutral solution of peroxide of hydrogen, it becomes covered with bubbles of oxygen, part dissolving with a substitution value of $Ag_2 = 216 = H$. The plate of silver becomes coated with a greyish white film, and then a small quantity of greyish blue powder is precipitated. The solution darkens in the air, taking a reddish brown tint, and becoming slightly turbid from the separation of finely divided silver. When the hydrated argentous solution is evaporated, a colorless crystalline substance is left, which, treated with water, dissolves, leaving silver. The filtrate contains argentic hydrate ($Ag = 108 = H$) and has a feeble alkaline reaction. With hydrochloric acid it gives a precipitate of chloride of silver. Argentous hydrate in solution gives, with potash, a brown black precipitate (argentous oxide). With hydrochloric acid it forms, after a certain time, a precipitate of chloride of silver and metal. These reactions may be expressed by the following equations :—

$$2Ag_2 + H_2O_2 = 2HAg_2O.$$

(Argentous hydrate)

$$2HAg_2O = 2HAgO = 2HAgO + Ag_2.$$

(Argentic hydrate.)

$$2HAg_2O + 2HCl = 2H_2O + 2AgCl + Ag_2.$$

The solution of argentous hydrate is not precipitated by sulphuretted hydrogen. On evaporation metallic silver separates. When oxide of silver is added to oxy-water, it is known that the oxide is reduced with a brisk disengagement of oxygen; at the same time argentous hydrate is formed by the action of peroxide of hydrogen on the finely divided silver. The author is engaged in the examination of the grey coating which forms on the silver; he believes it to be peroxide of siver.

"*On the Existence of an Amyloid Matter in the Yolk of Egg*," by M. Camille Dareste. The author finds that in the yolk of egg there exists a considerable quantity of microscopic granules which become coloured blue under the influence of iodine, and whose form and structure exactly recall those of starch. Their size varies greatly; ordinarily they are very small, but some are met with as large as the largest granules of wheat starch. On these, concentric layers and a central nucleus are seen; these granules are very difficult to recognise.

"*Experiments on Superheated Steam*," by MM. G. A. Hern and A. Cazin.

"*On Silkworm Disease*," by M. Béchamp.

January 8, 1867.

(FROM OUR OWN CORRESPONDENT.)

M. LEROUX read a paper "*On Luminous Vibrations*," the conclusion of which is that the incident and reflected vibrations are (in direction) the projections of the refracted vibration upon the incident and reflected waves. This is MacCullagh's theorem.

M. de Caligny again calls attention to the means of economising water in the working of locks.

M. Maigne communicates an easy method of deter-

mining the nitrogen of manures in operating on only 50 grammes.

M. Carus, of Dresden, a correspondent, thinks it his duty to call the attention of the Academy to a remarkable case of preservation from cholera during the epidemic of 1866. A whole town had been attacked, and already there had been 119 victims. It was greatly feared that it would spread to a prison containing 1250 inmates, and recourse was had to very simple prophylactic means, but which proved very efficacious:—1st. Every day the excremental matters were disinfected by throwing into them ashes or fragments of lime, or treating them with chlorine or pyrogallic acid. 2nd. The diet of prisoners was improved. 3rd. The wards were disinfected, and the clothing and bedding were so disposed as to prevent any sudden cold. 4th. Each individual was daily submitted to an examination to ascertain the state of his health. 5th. Moral influences of different sorts were exerted to quell any alarm calculated to predispose the body to morbid invasion, &c. Thanks to these precautions, the entire prison was preserved.

M. Becquerel, in his name and that of his son, M. Edmund Becquerel, presented a new series of observations, thermometric and hygrometric, taken simultaneously in free air and under trees, the general results of which may be summed up as follows:—In summer the mean temperature in free air slightly exceeds that under the trees; in winter the contrary is the case. The trees, in spite of their inferior conductibility, assume a temperature in equilibrium with that of the air, but very slowly. The diurnal maximum takes place towards midnight under the trees, whereas it occurs towards 3 o'clock in the afternoon in free air. A little more rain falls three kilometres from the wood than at its verge or in the interior. The climate under the trees is a sort of sea-climate, and this conclusion of the thermometric and hygrometric observations is confirmed by numerous facts of vegetation.

M. Henry St. Claire Deville laid upon the table a note, compiled by him, in connexion with M. Wöhler, "*On a New Alloy of Aluminium and Boron.*"

General Morin read a new note on the immense reservoir, constructed at the expense of the town of Saint-Etienne by M. Krauss, engineer of bridges and roadways, to store up the waters of the Furens and other watercourses which are changed twice a year into torrents. The total capacity of the basin is 528¾ millions of gallons, and as the wants of the town require only 132 millions, there remain at disposal 396¼ millions of pure and wholesome water; at the same time all danger of inundation is avoided. The sum expended by the town is certainly enormous, but the concessions of water bring in 5 per cent. of the money laid out, without counting the considerably increased value of the factories belonging to it.

M. Velpeau calls attention to the "anamo-inamovible" bandages of silicate of potash or soluble glass, which advantageously replaces albumen, starch, dextrin, papier maché, plaster of Paris, &c. The most valuable property of the bandage of soluble glass is that of promptly drying in two or three hours, and of easily becoming soft with water.

M. Balard communicates a new and very important discovery by M. Berthelot,—the synthetic production of oxalic acid by means of superoxygenated acetylin in contact with permanganate of potash. This transformation of acetylin into oxalic acid is easy and prompt, and takes place in rather considerable proportions. As the bi-carburetted hydrogen or common street gas is acetylin *plus* hydrogen, it is also transformed into oxalic acid, but in a less proportion, and mixed with foreign substances. It is truly curious to see these three mineral substances—carbon, hydrogen, and oxygen—arrive, by their successive addition, to produce an organic substance, oxalic acid: carbon + hydrogen = acetylin, acetylin + oxygen = oxalic acid. It is certain that by making permanganate of potash act on carburets analogous to acetylin, amylin, ethylin, &c., we can produce other syntheses not less interesting than oxalic acid.

M. Charles Grad seemed disposed to conclude from the experiments of M. Bertin on ice, and from an attentive study of the glaciers of Mont-Rosa, that we must renounce looking to the viscosity of Mr. Forbes, or to the regelation of Professors Tyndall and Faraday, for the explanation of the movement of glaciers, to revert to the ancient theory of dilation of M. Chapentier.

It may be recollected that M. Desnoyers, librarian to the Museum of Natural History, Paris, and Member of the Academy of Inscriptions and Belles-Lettres, had remarked on a great number of fossil bones, of the strata of Saint Prest, near Chartres, scratched grooves or cuts, which he attributes to the hand of contemporaneous man. He alluded to some on the bones of the *elephas meridionalis*, the *rhinoceros lepthorhinos*, *&c.* Many geologists, M. Bayle among others, of the *Ecole des Mines*, did not see in these marks anything but injuries purely accidental, occasioned by the surrounding pebbles, or the hand which had extracted the bones from the surrounding clay; and they brought as an argument against the interpretation of M. Desnoyers, the fact that in these quarries no ancient remains of human industry had been found. M. Archiac is informed that this objection is at present without foundation, since the Abbé Bourgeois de Pontlevoy, the celebrated collector, has found in the Saint Prest beds shaped flint implements of various forms—hatchets, arrow-heads, &c.

M. Fremy presents, in the name of M. Louis Fiquier, his work—"*l'Année Scientifique et Industrielle, ou Exposé Annuelle des Travaux Scientifiques des Inventions, et des Principales Applications de la Science à l'Industrie et aux Arts que ont Attiré l'Attention Publique en France et en l'Etranger*," a volume in 12mo, of 500 pages, published by Hachette. All we can say is, in echoing the words of M. Fremy, that this volume is in every way equal to its predecessors.

M. Leverrier communicated a letter addressed from Algiers to M. Wolff by a commandant of Artillery on the earthquake of January 3. Five or six shocks were counted, the most violent of which was that which took place at 7h. 13m. It made the extremity of the conical pendulum mounted as a seismometer, or apparatus for indicating earthquake, form an abnormal curve of amplitude of some extent, which M. Leverrier placed before the eyes of the Academy, and which represents very well the successive oscillations of the ground, first north-west, then north, west, east, west, &c.

January 14, 1867.

(From our own Correspondent.)

M. Matteucci informed the Academy of his researches on the adhesion of air to metallic surfaces. He heats plates of platinum in a current of oxygen or hydrogen; then he places them, while yet hot, in closed apparatus containing one of the above-named bodies. Immediately there is a diminution of volume of the gases, and formation of aqueous vapours by the combination of the oxygen and hydrogen. It may happen in this case that (for platinum) the adhesion of the gases is not only to the metallic surface, but also in the interior of the metal itself. Every one, in fact, knows that metallic platinum is generally formed by hammering spongy platinum, a substance which has the property of exciting the combination of a certain number of gases together; hence it will not be unreasonable to believe that the molecular interstices, opened by the heat, would retain the gases, and thus cause their combination under the influence of other bodies in contact with them.

M. Sommet, a pupil of M. Wurtz, on account of the accidents which unfortunately too frequently happen in

coal mines subject to firedamp, proposed to introduce into all the drifts electrical conducting wires, so that, on several points, during the absence of the men, the inflammable gases may be set on fire by interrupting the electrical circuit. By this means, he said, the numerous deaths might be avoided which during the last month have brought desolation into the families of the colliers and the neighbourhood.

M. Linguet addressed to the Academy a long research upon the electric influences relative to atmospheric meteors. He endeavoured to explain all the rains we had during the past year, the hail, thunder, cold, heat, drought, &c., by electrical phenomena, which take place in the atmosphere. Also, he indicates the means of preserving us from these more or less disastrous meteoric phenomena. We regret extremely that M. Chevreul did not say a few words on the means proposed by M. Linguet.

M. Blondeau (of Nancy) sent a memoir relative to the detection of stains of blood upon linen in the case of legal surgery. All persons occupied in legal medicine comprehend the great interest attached to similar labours; for after the linen has been washed the stains resemble very much stains of rust or ironmould, or marks which certain organic acids or vegetable colouring matters would leave. These are the principal characters indicated by the author:—1st. Stains of rust or ironmould are clear and dull; blood stains are of a deeper colour, and shining. 2nd. If heat be applied up to 25 or 30° C. to the suspected object, blood stains will scale off and are easily detached, whereas ironmould remains. 3rd. If the linen be wetted with hydrochloric acid the ironmould is dissolved, while blood stains remain unaltered. In the former the presence of iron is at once indicated, but not so in the latter. 4th. The stains of acid fruits with iron are hygrometric and soluble in water. 5th. The microscope should be employed, in order to recognise directly the globules of blood detached from the linen and dissolved in oil.

Mr. Phipson communicates the results of his analysis of the sands found in Oceania, in the torrents, which are a compound of argil, apatites, calcareous substances, pyrites, titanate of iron, and small particles of *diamond*. It is always found in soil brought down by the waters in the midst of sands which form the bed of rivers. Thus, the memoir of Mr. Phipson confirms the previous information, and proves that in all modern soil brought down by water, search should be made for this precious substance. The analysis showed it to be in the proportion of $\frac{1}{1000}$ of the land.

M. Pelouze presented an important memoir on the manufacture of glass. It is well known that this substance is fabricated by mixing 100 parts of sand, 40 to 45 of sulphate of soda, 80 of powdered charcoal, 6 of slaked lime, and 20 to 50 of old glass broken up, in crucibles or pots, which are submitted to a great heat. The formula of glass is about $CaO(SiO_3)^2 + (NaO)KaO(SiO_3)^2$—that is to say, a bisilicate of lime and potash or soda. M. Pelouze has discovered that if one would wish to change the reciprocal proportions of the bodies which practice and analysis have fixed, new substances are obtained, and he showed, in confirmation of this, some very remarkable specimens. One in which the proportion of silica had been increased to 400, represented the porcelain called *de Reaumier's*—that is to say, an opaque substance, and analogous to the translucent marble called Algerian. The other specimen, in which the proportion of alcali was greater than usual, formed a very attackable glass; if the alumina be increased we obtain a scoriform non-vitrifiable mass. The learned *savant* then made some observations on the presence of sulphur and oxide of iron in materials of the glass. Experiments proved that a small quantity of sulphur gave a green tint, and that if the glass so coloured be heated it becomes yellow; if it be cooled, the sulphate of soda is reduced, and the green colour appears.

M. Pouillet read a report serving as instructions for fixing lightning conductors to powder magazines. The Minister of War, it appears, had great fears that the powder magazines might be set fire to by lightning, and in order to prevent this he asked the Academy for new instructions for establishing preservative apparatus.

NOTICES OF BOOKS.

*Traité Pratique d'Analyse Chimique.** By F. Wöhler, F.R.S., Professor of Chemistry at the University of Göttingen, Foreign Associate of the Institute of France. Paris: Gauthier-Villars.

This little work was originally written for the use of the students at the University of Göttingen, and an English translation of the first German edition was published by Dr. Hofmann 13 years ago. Since that time chemical analysis has undergone such great changes that the present edition may be almost considered a new work. It is a French translation of the latest German edition, by MM. Grandeau and Troost, who have enriched it by several original methods. Dr. Wöhler's work in its present form is adapted not merely for a book of instruction for chemical students, but also for a standard work of reference on chemical analysis, its suitability for this purpose being greatly increased by the alphabetical "analytical table," with which it commences. The preface to the book so clearly expresses its value that we are induced to quote it in full. The author says:—

"I have been guided in my choice of the plan of this work by the conviction that it is easier for most minds to ascend from individual facts to general laws and rules, than to descend from general rules to individual cases. It has, therefore, been my object to write a book that should leave both something for the pupil to reflect upon, and something for the master to explain. I leave to the latter the double care, where he may think it advisable, to point out the names of the inventors of the different methods, and to pronounce upon the relative value of the processes described. The systematic order has not always been followed in the description of the analytical processes, but the tables at the commencement of the work will greatly facilitate reference.

"With respect to the plan and spirit of this treatise, I have nothing to add to the preface of the second German edition I have lately brought out. I will merely say that the French translation is not a simple translation, but a new edition, enlarged and corrected by the labour of my two learned friends, MM. Grandeau and Troost. Theirs is the merit of having given it, by numerous well chosen additions and instructive diagrams, a perfection that the German original is very far from attaining."

We do not propose now to give any further extracts, as we have arranged, through the courtesy of Professor Wöhler, that the novel and beautiful methods of analysis, of which he is so great a master, may be published in detail in the pages of the Chemical News.

We will, therefore, at present only add that the arrangement of the matter is all that could be desired, while the name of the author, who is admitted to be *facile princeps* in minute and accurate mineral analysis, is a sufficient guarantee of the great value of the processes which will now, for the first time, be laid before English chemists.

CORRESPONDENCE.

A Miniature Museum.

To the Editor of the CHEMICAL NEWS.

SIR,—Your correspondent, "A Student," who writes in your last number respecting the arrangement of chemical specimens, has introduced a subject which I am sure will interest a large class of chemists. I hope several of your correspondents will be induced to give us the results of their experience, and, as a contribution to the general fund of knowledge, I beg to forward my mite.

I have two or three drawers in my laboratory fitted up as follows:—They are 12 inches wide, 18 inches long, and 4 inches deep. I procured two pieces of perforated zinc with holes about $\frac{3}{4}$-inch diameter and as close together as possible. These were 12 by 18 inches, and were so cut that when laid one on the other the perforations should exactly coincide. One of these pieces was screwed (on small blocks) into the drawer about one inch from the bottom, and the other piece of zinc was fastened in a similar manner one inch from the top, a space of about two inches being between the two zincs. Next I had 18 dozen of glass tubes made, sealed up at one end, a little thicker than test tubes, and having the mouth not turned over, but only just softened in the blowpipe, so as to take off the cutting edge. These were a trifle smaller in diameter than the holes, were $3\frac{1}{4}$ inches long, and being fitted with corks, were placed upright in the holes in the zinc plates. They stood very firmly and in perfect order in 18 rows, 12 in each row. In these I have commenced to arrange my chemical specimens. They are labelled by writing with a fine pen on the corks, a duplicate label being held *in* the tube close to the side by the cork.

This plan has the advantages of occupying very little room and being cheap. In a small drawer I have 216 specimens in perfect order, and the whole expense was under twenty shillings.

I am, &c. ANOTHER STUDENT.

R. C. C., January 14.

Gas from Charcoal—Soluble Vegetable Fibre.

To the Editor of the CHEMICAL NEWS.

SIR,—Mr. William Skey opens a paper, contributed to your last impression, with the words, "As far as I can learn, it is generally supposed that the gas escaping from charcoal when put in contact with water is common air—and, indeed, I am not aware that any different opinions are, or ever have been, entertained."

He cannot know, then, that last year Drs. Blumsritt and Reichardt published an extensive series of researches about the gases absorbed by solid bodies (*Chemisches Centralblatt*, 1866, pp. 689. 705, 753, 769). Their paper has most likely not yet been noticed in English chemical periodicals. The *Journal fur practishe Chemie*, of Sept. 30, 1866, seems to contain the same papers, according to the notice in your "Contemporary Scientific Press" of last week.

Dr. Blumsritt found in one case the gas absorbed by charcoal to consist of pure nitrogen; but in most cases it contained carbonic acid, and sometimes oxygen, though never as much as atmospheric air.

With reference to Mr. Skey's paper in your last impression but one, "On the Effect of Ammoniated Solution of Copper on Vegetable Fibre," he will derive much information on the same subject from the innumerable and exhaustive researches published some seven or eight years ago by MM. Schwerzer, Naegeli, Pelouze, and many other eminent chemists, most of them German or French.

I am, &c. G. L.

South Shields, January 14, 1867.

Ansell's Firedamp Indicator.

To the Editor of the CHEMICAL NEWS.

SIR,—A great mass of correspondance has appeared in the papers upon the subject of Ansell's Indicator. Great injustice has been done to that gentleman in two particulars mainly—First, that Lord Kinnaird's statements about the proper ventilation of certain mines (which may or may not be founded in truth) have been promiscuously involved in the efficiency of a certain instrument; and second, they have attributed a desire on Mr. Ansell's part to enforce compulsory adoption of his indicator in default of the approbation of the instrument by men well versed in the subject and most practically informed in the bearing of all details. The evidence of Mr. Ansell certainly entirely disposes of the second cause of complaint. But a third question remains which I feel more doubt about. Have any results been yet published as to the actual practical working of the instrument? Have any engineers given evidence in its favour? And lastly, is it true that Mr. Ansell acted in a manner to convince the public generally of the value of his instrument, when he met certain objections with the reply that each and every one of them was simply untrue? Again, can a laboratory experiment, more or less theoretical in per centage, &c., replace a practical investigation, where all sources of fallacy are co-operating? A serious charge I also copy: "Mr. Ansell himself has drawn the especial attention of the Select Committee on 'Mines' to the fact that his indicator does not always indicate correctly, with the alarming excuse for the failure of the instrument in the experiment mentioned that 'it was agreed that this was held 10 seconds too long, as the index hand travelled backwards.'" Of course, the objections to the working of the machine rationally show an utter want of comprehension of the instrument. Mr. Ansell can hardly be expected to answer in a rational manner the observations of a writer who talks against insulating wires because they would look like a spider's web, radiating from a common centre (the manager being the spider in the middle); of the tiny poles of the little battery—"of the tinkling of the little bell." The only way to suppose that the author in such words discusses the practical applications of a well thought out scheme is, that such language is used as a cloak to confusion of ideas; or that it is what is now called a prose poem. I am inclined to think that the author of the letter referred to is a poet.

I am, &c.

DON'T BLOW UP.

Iodine in Mineral Phosphates.

To the Editor of the Chemical News.

Sir,—In reference to the occurrence of iodine in phosphorite, I would mention that it seems probable that this element will more frequently be met with in phosphorites if proper search is made for it.

Besides in the phosphorite of Nassau, as cited by your correspondent "F.," iodine has been found in the phosphorite of three localities in Bavaria—namely, in that of Redwitz, Fuehsmühl, near Waldrassen, and Amberg. The latter occurrence is the more important one, and it is the mineral of this locality in which the presence of iodine was first noticed by Alex. Müller and by W. Mayer.

The quantity of iodine in this mineral is so minute that it will escape observation in an ordinary analysis. Its presence is, however, readily rendered visible by placing the powdered mineral, mixed with glass-powder, in a flask, pouring strong sulphuric acid over it, and allowing the whole to stand for some time, when violet vapours of more or less intensity will make their appearance. As phosphorites from various localities are so often subjected to analysis, it would be a matter of interest if chemists would avail themselves of the opportunity, and make the additional simple experiment for the purpose of ascertaining the presence of iodine.

I am, &c. H. M.

Arrangement of Chemical Specimens.

To the Editor of the Chemical News.

Sir,—"Student" asks how best to arrange chemical specimens. I have devoted some attention to this subject for many years, having had the arrangement and curatorship of a tolerably extensive chemical museum. As the result of my experience, I would strongly advise that the classification should be strictly that followed in Gmelin's chemistry. It may be arbitrary, but I know of no other which so clearly and absolutely defines in a collection the proper position of any chemical compound.

There is only one drawback which I cannot quite get over to my satisfaction—that is, it requires the proximity of bottles of all sizes and shapes, and thus interferes with the neat appearance of the cupboards. This objection is, however, trifling in comparison to the great convenience of the plan of arrangement.

I am, &c. M. P. S.

MISCELLANEOUS.

Poisoning by Sulphuretted Hydrogen.—On Thursday, the 10th inst., Mr. Richards, the deputy-coroner, instituted an inquiry under the following circumstances:—Two men had been ordered by the foreman at the Iceland Chemical Works, Bow, to empty a tank containing sulphate of ammonia. A third workman shortly afterwards found one of them partly in the tank for the purpose of fitting a syphon to draw the liquor off, taking a light down into the tank with him. The other workman was standing on a stage close at hand, when the man who had descended into the tank returned with the light out, and asked to have it relighted; he was asked what put it out, but did not answer. The lamp being relighted another descent into the tank was made by the same workman, who was next seen by the person who found the two men together, to lean his face on his hand, and fell into the liquor in the tank. The deponent Harley, on seeing this, immediately went down the ladder, succeeded in seizing the arms of the suffocated man, but became insensible himself. A clear statement of what followed was not given, but Harley was saved, and the other two men were suffocated by sulphuretted hydrogen gas. It was stated that a similar accident nearly happened to one of the deceased a few weeks previously. The verdict of the jury amounted to an expression of their opinion that the foreman of the works was much to blame. No doubt much obscurity exists in the above case, but enough is learnt to show three things—gross carelessness somewhere, loss of life, and nobody responsible. But it also serves as an antithesis to the late colliery accidents and loss of life, and, like them, shows that the work of supervision in works where many sources of danger are rife, from the largest to the smallest, is utterly bad. The ordinary workman is not to be relied upon; he wants continual supervision, and this is not provided. Thus, in the present case, when warnings of danger had been given, by the flame of the lamp being extinguished by some noxious gas, a descent was still persisted in; so in mines where gas has been known to be accumulating, the flame of the lamp has been exposed by the workmen for the purpose of lighting their pipes, and, if not so bad as this, matches have been carried about for the same purpose. Instances might be multiplied of this carelessness and its evil results. Our object is not so much to state over again what everyone knows, but to show that for the recurrence of such accidents to be prevented, a responsibility must be recognised as belonging to some one person who may be legally punished for a neglect of duty. The public certainly will never tolerate applications of chemical science to manufactures, if all precautions be not taken against such loss of life, whether it be on a large or a small scale.

Decimal Weights and Measures.—The Astronomer-Royal has sent the following to the *Athenæum*:—"In the last week's *Athenæum*, page 9, column 3, I observe the following remarks:—'We should hail a *Permissive* Bill in favour of *allowing* the decimal subdivisions of a mile, a foot, a pound, a gallon, &c., to contracting parties who wish for them.' 'Sir John Herschel is also of opinion that decimals of our present units should be allowed.' I ask leave to make known to the public, through the *Athenæum*, the present state of the British law on this subject. In the 'Act to Render Permissive the Use of the Metric System of Weights and Measures,' 27 and 28 Vic. cap. 117, section 2, is the following provision:—'Notwithstanding anything contained in any Act of Parliament to the contrary, no contract or dealing shall be deemed to be invalid or open to objection on the ground that the weights or measures expressed or referred to in such contract or dealing are weights or measures of the metric system, or on the ground that decimal subdivisions of legal weights and measures, whether metric or otherwise, are used in such contract or dealing.' This appears to contain all that is desired in the *Athenæum*. I greatly doubt whether extensive advantage will be taken of this permission, at least, until we have a decimal coinage. I know of only three instances in which the decimal subdivision is really useful—the decimal division of the foot on surveyors' levelling-staves; the decimal division of the avoirdupois pound in certain operations for tare, by rule-of-three, in the Custom House; and the decimal subdivision of the troy ounce for bullion. In the first two of these, the persons concerned introduced them without waiting for an Act, and in the third they promoted a special Act. In ordinary cases, where there are facilities both for decimal and for binary subdivision, (as the mile of eighty chains, the ton of twenty hundredweight), the decimal subdivision is never used. One of the most curious instances, showing the tendency of mankind to adopt some special weight or measure as the standard for some special goods, and then to subdivide it, not by decimalising, but by successive halving, is that of the stone of fourteen pounds, used throughout Britain as the standard weight for flour, oatmeal, salt, &c. In Scotland it has long since been halved and halved down to the one-sixteenth part, or fourteen ounces, there called the 'meal-pound.' In Lancashire it is halved and halved; and applications have been made by the local authorities to the Exchequer for standards of three and a half pounds."

Copper Smoke.—For generations past efforts have been made to utilise or neutralise the smoke emitted from the various copper works of the kingdom, which is known to be so injurious to all vegetation around. In the neighbourhood of Swansea, which is the principal seat of the copper trade, there are thousands of acres with hardly a blade of grass upon the ground, and in many instances the smelters have had to pay heavy damages for the injurious effects of the smoke on adjoining properties, even trees many miles distant being affected. About twelve months ago Mr. H. H. Vivian, M.P., adopted an invention at his works in order to see whether something could not be done to abate the nuisance, and, if possible, utilise the smoke as well. A considerable outlay was incurred in giving a thorough practical test to the invention, and at the meeting of the West Glamorgan Agricultural Society Mr. Vivian announced that his efforts had been crowned with entire success. The smoke is condensed, and by judicious admixtures a very excellent superphosphate is produced, which is especially suitable for root crops. Mr. Vivian calculates that in a short time he will be able to produce annually sufficient manure for 40,000 acres of land. The success attained will no doubt induce other copper smelters to follow the example, and many thousand acres, which are now almost a barren waste, will then be made fertile ground.—*The Times.* [Our readers scarcely require reminding that "copper smoke" does not make superphosphate of lime; it is merely condensed for the purpose of producing oil of vitriol; the phosphates, bone ash, sombrero, coprolites, &c., have to be purchased in the usual way, and treated with sulphuric acid, the product of which is superphosphate of lime.]

Skeleton Leaves.—"The following method has been communicated to the Botanical Society of Edinburgh:—'A solution of caustic soda is made by dissolving 3 oz. of washing soda in 2 pints of boiling water, and adding 1½ oz. of quicklime, previously slacked; boil for ten minutes, decant the clear solution and bring it to the boil. During ebullition add the leaves; boil briskly for some time—say an hour—occasionally adding hot water to supply the place of that lost by evaporation. Take out a leaf and put it into a vessel of water, rub it between the fingers under the water. If the epidermis and parenchyma separate easily, the rest of the leaves may be removed from the solution, and treated in the same way; but if not, then the boiling must be continued for some time longer. To bleach the skeletons, mix about a drachm of chloride of lime with a pint of water, adding sufficient acetic acid to liberate the chlorine. Steep the leaves in this till they are whitened (about ten minutes), taking care not to let them stay in too long; otherwise they are apt to become brittle. Put them into clean water, and float them out on pieces of paper. Lastly, remove them from the paper before they are quite dry, and place them in a book or botanical press.' Dr. G. Dickson."—*Hardwicke's Science-Gossip.*

A Flash of Lightning.—A *Smatterer* writes:—A stout iron hook, part of a set of block pulleys, snapped while an iron casting weighing near four tons was being lifted. The iron was found defective in texture and in forging. At the moment of breaking a bright flash of light was distinctly seen between the broken fragments. Is this a usual phenomenon? If so, what is its nature, or how accounted for? This occurred in broad daylight, with fine, drizzling rain falling at the time; and the flash was described as from eighteen inches to two feet long.

On the Reactions of Morphine and Narcotine,* by M. Husemann.—M. Husemann's process for distinguishing morphine consists in dissolving the matters to be tested in concentrated sulphuric acid, and adding a drop of nitric acid to the solution. If morphine is present, it immediately produces a coloration varying from rose to the most intense carmine, and by heating for some minutes to 100° or 150°, a magnificent violet colour appears, which afterwards changes to blood-red. Narcotine becomes bluish-green in cold sulphuric acid, turning violet-red by the action of heat.

Quekett Microscopical Club, at 8 p.m. Dr. Sedgwick, "*On a Moveable Stand carrying Lamp and Microscope.*" Mr. C. A. Watkins, "*On Yeast and other Ferments.*"

Saturday, January 26.

Royal Institution, at 3 p.m. G. A. Macfarren, Esq., "*On Harmony.*"

ANSWERS TO CORRESPONDENTS.

Vol. XIV. of the Chemical News, containing a copious Index, is now ready, price 11s. 0d., by post, 11s. 6d., handsomely bound in cloth, gold-lettered. The cases for binding may be obtained at our Office, price 1s. 6d. Subscribers may have their copies bound for 2s. 6d. if sent to our Office, or, if accompanied by a cloth case, for 1s. Vols. I., II., and VII. are out of print. All the others are kept in stock. Vol. XV. commenced January 4, and will be complete in 26 numbers.

Tyro.—We presume Dr. Calvert meant that acetylin was the richest *gaseous* hydrocarbon known.

Electric.—Du Moncel's book on the Induction Coil will give you all the information you require. It can be obtained at Asher's.

Steatite.—J. C., who inquired about this article a week or two ago, is informed that several letters giving him the desired information are waiting for him at our office.

G. L.—Chemical Text-book.—The question arrived too late to be answered last week. We are of opinion that Dr. Roscoe's little work on Chemistry, reviewed some months back in our columns, will be as good a one for your purpose as any you can have. We beg to express our obligations to G. L. for his communications.

Erratum.—In the contents of the "Bulletin de la Société Industrielle de Mulhouse," vol. 36, the paper "On the Comparative Solidity of Thickeners composed of Lucine and Albumen," by *J. Roberts* and A. Rosenstiehl, the authors' names should have been "*Robert Wilson Thom* and A. Rosenstiehl." The error, which we hasten to correct, was copied from the Bulletin.

Specific Gravity.—To find the true specific gravity of coke, it should be reduced to the finest possible powder, then weighed in air, and afterwards in water, boiling it well in the water first to be sure that all air is removed. Unless you take these precautions, the specific gravity will be too low from adherent air. A very beautiful piece of apparatus for ascertaining the specific gravity of porous bodies has been devised by Professor Leslie, and is described and illustrated in Faraday's Chemical Manipulations, p. 53.

Blowpipe Analysis.—The woodcuts for this paper have not been finished in time for insertion this week.

Querist.—Fat lute is made by beating dried and finely-pulverised pipeclay with drying linseed oil until the mixture be soft and ductile. It is to be closely applied to the junction intended to be made tight, the glass or other substance being first wiped perfectly dry. Common glaziers' putty resembles this lute, and will in most cases answer the same purpose.

Medico-Legal.—You can obtain the magnesium rods at Mr. How's, Foster Lane. The other chemicals and apparatus you mention can also be procured at the same place.

J. MacVicar.—You will find nothing so good as Condy's *crimson* fluid for removing the fetid odour complained of. The *green* fluid will not answer your purpose so well.

CS_2.—*Extraction of Grease.*—If CS_2 will address E. S., 2, Albert Road, Forest Lane, Stratford, E., information can be given where an apparatus as mentioned can be seen at work.

Books Received.—"Practical Chemistry," by S. Macadam, Ph.D., &c.; Dr. Hunter *v. Pall Mall Gazette:*" "Matter: its Ministry to Life in Health and Disease; and Earth—as the Natural Link between Organic and Inorganic Matter," by Thos. Hawksley, M.D., &c.; "The Elements," Vol. II., by W. Layton Jordan.

Received, with Thanks.—R. Warington, jun.; F. V.

LIME-JUICE AND SCURVY.

A discussion has been going on for some time respecting the value of lime-juice as an antiscorbutic. Chemistry is capable of throwing considerable light on the subject, and we wish to draw attention to one or two points in connexion with it. Dr. Stone, in a letter to *The Times*, says:—

"In the absence of fresh succulent vegetables, lime or lemon-juice must take the foremost place; that it contains something of a specific nature we know—what that something is we have yet to discover; certainly not citric acid, for this, notwithstanding what has been asserted by some writers, is worthless."

Dr. Stone proceeds to say that potash salts stand next to lime-juice in value, and are stated by Dr. Garrod to be the deficient ingredient in the blood of scorbutic persons. This is scarcely stating the case strong enough. It is believed by Baron Liebig and other high authorities that the specific in lime or lemon-juice which "we have yet to discover" is actually the potash which it contains, and examination certainly appears to support this view of the case.

Lime-juice is used in the English navy and merchant service as an efficient antiscorbutic. Amongst American seamen scurvy is almost unknown, and this immunity has been ascribed to the very general use of potatoes; whilst in France and Russia the rareness of this disease is similarly ascribed to the almost universal consumption of thin light wines as a beverage. Rice, which has been frequently proposed as a substitute for potatoes, has, however, been proved to be utterly valueless as an antiscorbutic. Again, the evil effects of salt meat are notorious, but fresh beef alone is capable of preserving health for almost any time.

These facts are found to agree perfectly with the potash theory of scurvy. The mineral constituents of lemon-juice are found to be extremely rich in potash, containing, according to Mr. Witt, upwards of 44 per cent. of this alkali. There is an opinion that the juice of the lime (*Citrus limetta*) is stronger and more acid than lemon-juice, but in chemical constitution there is not much difference between the two. Fresh vegetables, as a rule, are rich in potash salts; potatoes, which may be placed at the head, containing no less than 51 per cent. in their ash, according to Way and Ogston, and 55 according to Griepenkerl. Grape-juice, which may be considered as the representative of the light wines so largely used in the French and Russian marine, contains in its ash from 60 to 70 per cent. of potash, while the husks of grape have an ash containing 37 per cent. Rice, however, contains only 20 per cent. in its ash.

Dr. Garrod, who has examined various kinds of food in reference to this point, gives the actual amount of potash contained in different alimentary substances. From this we learn that—

One ounce of	rice	contains	0·005	gr. of potash
,,	lemon juice	,,	0·852	,,
,,	boiled potato	,,	1·875	,,
,,	raw beef	,,	9·599	,,
,,	salt beef	,,	0·394	,,

But without assuming that the active principle of these various antiscorbutic foods is the potash which they contain, there is no doubt whatever that chemical analysis is abundantly able to show the quality of lime-juice in an accurate and rapid manner. The constituents of lime-juice are not many, the organic part contains citric acid, mucus, vegetable albumen, pectin, and sugar; whilst the inorganic constituents, consist nearly half of potash, and the rest of the ordinary ingredients of the ash of plants. It is certain that most of these have no action as far as scurvy is concerned, and a little investigation could not fail to show whether the specific consisted of the potash or some other constituent. The work of the analyst would then be to see *generally* that the article was in a state fit for food and likely to keep, and *specially* to see that the percentage of the active ingredient did not sink below a certain standard. Too much stress has been laid on the considerable time which it is supposed lime-juice would take to analyse; and Dr. Leach has stated "authoritatively that any juice may be safely pronounced good, bad, or indifferent, in *from twenty to thirty hours* after its receipt by the inspecting officer." This is far longer than would be required. When once the appliances for such analyses were in working order, we do not hesitate to say that a skilful chemist would supply all the necessary information in a couple of hours.

Assuming, as will most likely prove to be the case, that the potash salts are the specific agents against scurvy, chemical analysis is seen to be indispensable in the selection of antiscorbutics for use on board ship. It then, however, becomes a question whether the active agent could not be stored and administered with far more economy, ease, and efficacy in the form of some convenient pharmaceutical preparation (such as the *granulated effervescing citrate of potash*) than when given through the exceedingly unscientific, clumsy, and ofttimes repulsive expedient of serving out lemon-juice to the men. It might also be worth while to ascertain whether the desired end could not be secured by letting chloride of potassium partially replace chloride of sodium in the preservative processes to which the provisions are subjected.

Whether every sample of lime-juice should be separately examined before shipment, or whether Dr. Stone's suggestion be adopted of licensing a limited number of lime-juice vendors, and occasionally verifying the genuineness of their commodity by analysis, is a matter which need not at present be discussed.

LONDON WATER: PAST, PRESENT, FUTURE.

PRESENT.

We gave in our last number a summary of the labours of a scientific commission, with a double aim—1st. To show the amount of accurate and concise information attainable by these means; 2nd. To show that the same questions that were answered then have to be answered now, after an experience of fifteen years. Of nearly

46,000,000 gallons then supplied, 20,000,000 gallons were taken from the Thames, leaving 26,000,000 gallons obtained from other sources. The New River Company water was chiefly derived from springs and small streams, and from the River Lea above Ware. The East London supply was from the Lea, six miles from its mouth, two miles beyond the tidal reach of the Thames; the Kent Company, from Ravensbourne; Hampstead, from the springs and artesian wells of that district; the Lambeth Company took the water from Lambeth (the lowest point then where water was obtained from the Thames); the Chelsea Company had their works at Battersea, above Vauxhall Bridge; the West Middlesex from Barnes; the Grand Junction from Kew Bridge. The West Middlesex and Grand Junction supplies alone were above the returning tide of the river.

Since the Report, the main source of the Lambeth supply has been removed to Thames Ditton, the highest point where water is taken from the river. The supply per head was 19·4 gallons. At present the supply is much greater, being over 30 gallons per head. As regards quality also the improvement is not less marked, and that chiefly from the filtration mentioned as being so necessary if the London supplies were still to be drawn so largely from the Thames. In 1851 the average hardness of the river water from all sources was 14·4 (by Clark's test); London water from other sources 15·3°, at present the respective numbers of degrees are 13·03 and 15·7. So the Thames water has been rendered a trifle softer, and the other metropolitan water is much about the same as it was. Dr. Letheby by his analyses has shown the great improvement in the amount of solid matter per gallon, which is lessened by from two to five grains in amount. Volatile organic matter is entered at present as 1 grain per gallon, against 1½ to 3 grains in 1851, as regards the Thames. So it may be said, indeed, that an improvement in quality has been effected in these respects, especially as regards the volatile matters; but the reduction in the whole solid matter per gallon is slight when compared with the quantity still in the water. Thus a reduction of 1 to 3 grains is almost insignificant when the totals range still from 18 to 20 grains in the gallon in the waters of the various companies. Dr. Letheby remarks that the quantity of organic matter in the metropolitan water is surprisingly small; as for the quality, there is no evidence, physical or chemical, to show that this is otherwise than harmless. As far as any test can be applied, it appears chemically, according to Dr. Frankland and Dr. Letheby, who have made the most extensive researches in the matter, that the present London supply is faulty chiefly as regards the hardness of the water, and that the East London Company's water is, if anything, rather better than the average.

(To be continued.)

Fire at Dr. A. Voelcker's.—On Wednesday, the 13th inst, a destructive fire occurred on the premises of Dr. A. Voelcker, 11, Salisbury Square, Fleet Street, which greatly damaged the valuable museum and collection of minerals, manures, &c., therein contained. We are glad to hear the contents were insured.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On the Application of the Blowpipe to the Quantitative Determination or Assay of Certain Metals, by David Forbes, *F.R.S., &c.**

The present communication is merely to be regarded as an introduction to a more lengthened and detailed treatise on the application of the blowpipe to both qualitative and quantitative research, which it is expected will be ready for publication before the expiration of this year. It is, however, hoped that the notes here brought forward may prove of some interest and utility to those chemists who hitherto may not have paid much attention to the employment of the blowpipe in the quantitative determination of those metals to which it has been found applicable.

It will doubtless be admitted that, in this country, but very little attention has been paid to the use of the blowpipe, and more especially to its employment in assaying; and it is probable that this result is in part due to the want of any satisfactory text-book in English for the guidance of the beginner, and in part also to the idea frequently entertained that a whole lifetime is required in order to attain any proficiency in its employment. Whilst, however, it is not denied that considerable practice and devotion to the subject is requisite for the development of the full powers of this instrument, still it is believed that, after a few trials, the beginner will be so encouraged as afterwards to follow up the subject *con amore*.

These remarks are more especially addressed to the traveller, whether mineralogist, metallurgist, or miner; for certainly the use of this instrument affords him means of obtaining expeditiously, and upon the spot, results which he could not possibly acquire without recourse to a chemical laboratory, seldom under such circumstances at his command.

For this reason also the apparatus here to be described, will be such as is more exclusively adapted for travelling purposes, from being as portable and occupying as little space as possible; and it may be stated that the complete blowpipe apparatus, which has safely accompanied the author in some seventeen years of rough travels in Europe, America, &c., and has been shaken in saddle-bags over thousands of miles without injury, is contained (balance included) in a small leather case measuring only twelve inches long, six broad, and ten and a half inches in depth.

Blowpipe.—Provided the blowpipe is furnished with a chamber for the condensation and retention of the moisture expelled with the breath, it matters little what form of instrument is used. The form adopted long ago by Gahn is considered, however, as the most convenient. Fig. 1 shows an improvement made by the author upon this form.

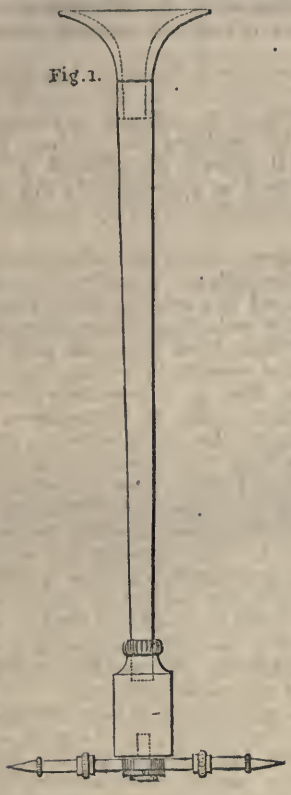
In this figure it will be seen that the arm of the jet is double, turning upon a central hollow axis, which allows the blast to be directed at will through either half of the arm, merely by rotating the arm itself half round; by having consequently the two holes with respectively a large and small orifice, a corresponding blast may be obtained at pleasure, without suspending the operation.

As a more steady and long continued blast is required in quantitative operations than could be kept up by using

* Communicated by the author.

a blowpipe provided with an ordinary mouthpiece held between the lips, without seriously distressing the muscles of the cheeks, it is quite essential that the trumpet mouthpiece, shown in Fig. 1, be adopted; for the same

Fig. 1.



reasons also the mode of holding the blowpipe represented in Fig. 2 is recommended as securing the greatest steadiness from motion, and as greatly assisting the muscles of the cheeks by the external support afforded them by the position of the thumb pressing against the trumpet mouthpiece.

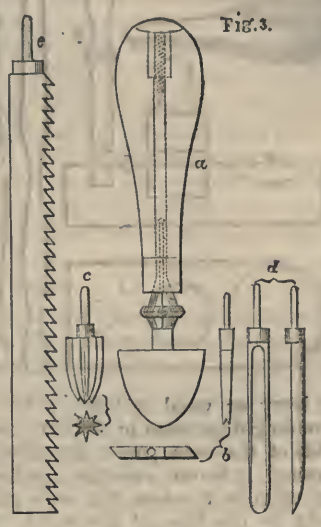
Fig. 2.

Combustible.—Olive oil, burnt in the usual Berzelius blowpipe lamp, is probably superior to any other. Gas is not to be recommended, as it is difficult to obtain a good reducing flame when using it. For cupellation and such other operations, however, which only require an oxidating flame, it is excellent.

Charcoal.—It is extremely difficult to obtain, in England, charcoal fit for blowpipe operations, without special preparation. The charcoal sold is generally of hard wood, badly burnt, full of cracks, and decrepitating upon application of heat. Good charcoal should be soft, yet compact, and without cracks, and is best made from fir or pine. Where good charcoal cannot be obtained it can be made artificially by moulding charcoal powder agglutinated by some starch paste, and, after desiccation, burning the pieces in a crucible filled with sand.

For the preparation of the charcoal used as a support for the assays, the instruments represented in Fig. 3 are required, all of which are fitted in the universal handle *a*, which is shown in this figure as holding the

Fig. 3.



largest charcoal borer, a section and plan of which are shown in *b*. This large borer is employed for forming the deep holes in the charcoal used in the blowpipe furnace, and which serve to contain the clay crucibles or capsules in which the assays are fused. The blast holes in the charcoal inside the blowpipe furnace are bored out by the gouge-shaped borer *d*, which also serves for making small holes or grooves in charcoal for general purposes. The smaller borer *c* is most useful, particularly in boring out the holes for receiving the soda paper cornets containing the assay for reduction. The sawknife *e* also fits into the same handle, and is used for trimming and sawing across the charcoal pieces, having coarse saw teeth in front, whilst the back presents a sharp knife edge. The figures are all drawn to one-half of the real size.

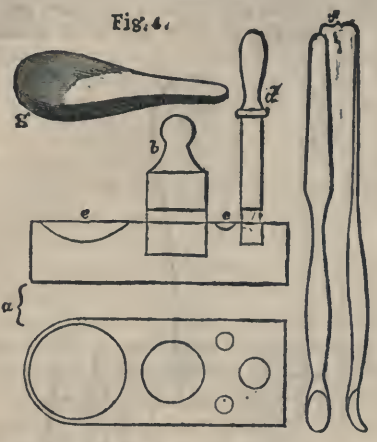
Instruments.—In the course of these notes any special apparatus required for the execution of the processes will be described, but other instruments, as forceps, lamp-trimming tongs, small hammer, agate mortar, scissors, magnifier, pliers, platinum wire, and holder, &c., are sufficiently familiar to everybody as not to require description.

Preparation of the Substance to be Examined.—In all cases the mineral substance to be assayed must be reduced to fine powder, as, if employed in grains, as is generally recommended in qualitative blowpipe examination, some loss by decrepitation is risked, and the flux employed would not act equally upon the assay.

A small diamond mortar is extremely convenient for breaking up the mineral into powder; but the steel instrument of the author, shown in Fig. 4 *a*, is recommended as combining both diamond mortar, anvil, and several other conveniences, whilst occupying the least possible space. In this figure it is seen both in section and in ground plan of its upper surface (the lower surface being merely a smooth plane for use as an anvil). At *b* will be noticed a small diamond mortar, whilst at *c* and *e* depressions of different depths and diameters are shown, which are found very useful in separating

the slag and metal beads from one another by a tap of the hammer, and for other purposes.

Fig. 4.



The small ivory or wood cylinder *d* fits so loosely in its corresponding depression in the anvil as to allow a couple of folds of the soda paper, hereafter described, to be rolled round it before insertion, and after withdrawal of the cylinder it leaves the soda paper cornet standing firmly in the hole of the anvil, which thus serves as a convenient stand for it whilst being filled with the assay.

All these figures, as well as those in Figs. 1 and 3, are correctly drawn to one half their real size.

Fig. 4 *g* represents a small scoop for mixing the assay with its flux before transferring it to its soda paper cornet, and is generally made of sheet brass or German silver; platinum is, however, preferable, as it occasionally will serve for heating a substance, and for the determination of ignition loss, or water, mercury, &c. Small scoops made of horn are made in Germany, and are, in default of platinum ones, employed when mercurial compounds are assayed.

Fig. 4 *f* is a small ivory spatula, and at the other end a spoon, and is used for mixing and weighing out. The spoon is used also as a measure for determining the quantity of flux to be added to the assay, in order to avoid the more tedious process of weighing the same.

Reagents.—The substances used in quantitative assaying are—Borax glass in two forms, as fine powder, and as small splinters of about the size of duck-shot; vitrified boracic acid in the form of powder; anhydrous pure carbonate of soda in powder (free from sulphate); monobasic phosphate of soda ($NaOPO_3$) in powder, formed by heating microcosmic salt to dryness; pure metallic arsenic in powder; arseniate of potash free from sulphate; anhydrous chloride of sodium, free from sulphate; pure graphite; pure assay lead, finely granulated; and bone ash in two states, as a moderately fine powder and as an impalpable levigated powder. In addition to these substances, the metals, iron, gold, and silver, as well as one or two compound fluxes, are required for some special operations, under which they will be treated of. As a general rule, weighing the quantity of these substances required in fluxing an assay may be avoided by knowing the amount contained in the small ivory spoon before described—for example, the spoon used by the author holds, when filled level, 6 grains of granulated lead, or 1 grain of anhydrous carbonate of soda, or 0·8 grain of pulverised borax glass, or 3·5 grains of powdered metallic arsenic, or 0·7 grain of powdered vitrified boracic acid, and so on; but naturally, as any two spoons may not be of exactly the same dimensions, each operator should find out these values for himself.

The substances should be well dried and kept in close-stoppered bottles, as it is quite impossible to obtain accurate results if reagents are used which are not anhydrous.

Soda-paper.—As it would be impossible to submit any powdered sustance to the direct action of the blowpipe flame without its suffering mechanical loss, some means must be employed for holding the particles together until they are so agglutinated by the heat that no such loss need be apprehended; this is secured by the use of the soda-paper envelope or cornet, as devised by Harkort.

For this purpose slips of thin, slightly-sized, writing paper, about one inch and a quarter long by one inch broad, are steeped in a solution of one part crystallised pure carbonate of soda (free from sulphate) in two parts of water. When dried these are used for forming small cylindrical cornets, by rolling them round the ivory cylinder Fig. 4 *d* previously described. A bottom is formed to them by folding down a portion of their length on to the end of cylinder, which is then pressed firmly into the corresponding mould in the blowpipe anvil, and which, upon the withdrawal of the cylinder, serves as a support until they are filled with the assay from the scoop, in which the assay and flux have been mixed. After pressing the assay down, the superfluous paper is cut off, leaving only sufficient, when folded down upon the contents of the cornet, to form a paper cover to the top similar to the bottom of cornet. The assay is then ready for placing in a bore in the charcoal, formed by the charcoal borer *c*, Fig. 3, and is then submitted to a reducing fusion.

Balance.—Any balance, which will weigh with accuracy to the one-thousandth part of a grain, will serve for blowpipe analysis; but as such balances are rarely met with sufficiently portable for travelling purposes, the author recommends one devised by himself in 1852 for this special purpose, and which is now constructed by Messrs. Ladd and Oertling, Moorgate Street, from whom it can be obtained. A description would, however, take up too much space in these columns.

The quantity of a mineral, to be employed in an assay, varies naturally with the character and fusibility of the substance in question, but from one to two grains will be found generally sufficient, unless the substance be extremely poor in the metal sought for, in which case it may be often advisable (as in some very poor argentiferous lead ores) to make two or more assays; and before finishing them to unite the half completed results, and then finish the assay upon the total. When great care is requisite, it is often advisable to make a rough preliminary assay, which serves as a guide in a subsequent more correct one.

The difficulty, in commercial assays, is not in getting accurate results of the assay actually operated upon, but in getting the small quantity actually employed to represent faithfully the whole bulk of the mass; in case of fused products, as regulus, speiss, &c., this difficulty is in great measure avoided.

(To be continued.)

On the Separation of Palladium and Copper, by F. Wöhler, *Professor of Chemistry in the University of Göttingen.**

I have lately discovered a new method for separating

* Communicated by the author.

palladium and copper. The mixed metals are dissolved in aqua regia, and the excess of nitric acid is driven off by heat. The liquid is then saturated with sulphurous acid gas, and a solution of sulphocyanide of potassium is added. This has no action upon the palladium, whilst it precipitates the copper in the form of a white subsulphocyanide, $Cu_2C_2NS_2$. This may easily be changed into Cu_2S or CuO, and the quantity of copper thereby ascertained.

Note on the Determination of Woody Fibre, by R. Warington, *Jun., Assistant to the Professor of Chemistry, Royal Agricultural College, Cirencester.**

In analysing a vegetable substance with a view to ascertain its worth as food, the chemist generally seeks to discover, among other things, the amount of insoluble woody fibre which it may contain; nor is this an unimportant part of his investigation, since the fibre is the most indigestible of all the food ingredients.

The general method of determining woody fibre is probably well known. The vegetable substance is first boiled in dilute sulphuric acid, which dissolves sugar, gum, starch, and the more delicate portion of the cellulose; the undissolved matter is then further boiled with a weak solution of caustic soda or potash, which removes fatty substances and albuminoids; the final residue is then, after suitable washing, &c., weighed as fibre.

A determination of woody fibre is clearly not a determination of the total cellulose present, but only of that portion of it which possesses a certain degree of insolubility; in a complete analysis both soluble and insoluble cellulose should be determined; but the latter, as most important, is that chiefly looked to in agricultural analysis, and to it the name of woody fibre is generally given.

It is much to be wished that this distinction of meaning between cellulose and woody fibre were carefully maintained in describing the composition of vegetable substances. The matter becomes exceedingly perplexing when determinations of insoluble fibre are spoken of as cellulose, and determinations of total cellulose as woody fibre. This confusion is very apparent in the tables contained in Watts' Dictionary; thus, according to one analysis there quoted, wheat bran contains 30 per cent. of cellulose, according to another only 9 per cent. Both of these figures appear as cellulose; the last is, however, without doubt, insoluble fibre. In the same way the cellulose contained in Indian corn is made to vary from 20 per cent. to 4 per cent., and the cellulose in wheat grain from 12 per cent. to 1·4 per cent. From what we know of these substances we may say with tolerable certainty, that the smaller numbers here given represent determinations of woody fibre, and not of total cellulose.

The method we have mentioned for estimating woody fibre will, of course, give various results if the acid and alkali employed are not always of the same strength. At the present time different chemists employ different strengths of acid, and though the stronger acid is generally allowed to act for a shorter period, the results of two laboratories are often in imperfect agreement. It is much to be wished that a definite strength both of acid and alkali were universally adopted.

There is, besides, a source of error I have not seen noticed, due to the presence of oily or fatty matter in the substance analysed. In seeds the oil is frequently found in intimate union with the outer membrane, which also naturally contains the chief part of the fibre. The oil thus associated with the fibre appears to protect it to some extent from the action of the acid, and thus the insoluble fibre finally weighed is really estimated too high.

In the following table the practical effect of this protective action appears; in one column is given the percentage of woody fibre, as shown by an experiment on the fresh sample; in the next column is the amount found after removing the oil by means of ether:—

	Woody Fibre before Removing Oil.	Woody Fibre after Removing Oil.
Linseed cake (1) . .	14·28	11·60
Linseed cake (2) . .	6·51	6·19
Cotton cake . . .	17·40	16·78
Wheat bran . . .	10·15	8·31
Indian corn meal . .	4·84	1·36

The error due to the presence of oil clearly varies a good deal; in the first linseed cake it is considerable, in the second practically nothing. The percentage of oil in each of these cakes was about the same, but their character, as shown by the proportion of fibre, was widely different; they represent, indeed, the maximum and minimum amount of fibre found in linseed cake. The most striking among the other examples is that of the Indian corn meal, which, after removing the oil, is seen to contain but 1·36 per cent. of fibre.

The possible source of error pointed to by these experiments is easily avoided. The oil is always separated by ether in the course of analysis, for the sake of determining its amount. The fibre can, therefore, be estimated after this operation without extra labour.

FOREIGN SCIENCE.

(From our own Correspondent.)

Paris, January 22, 1867.

M. Henry Berthoud has sent to M. Damour for analysis a specimen of an alloy, fabricated by the ancient races of the South American inhabitants, composed of copper, silver, and gold. It is in the shape of a thin plate, and is ornamented with figures in relief done by the hammer. On slightly bending it, it breaks. The colour is of a pale red tint, like that of copper. Specific gravity 10·41 (water = 1), and fusibility about the same as that of gold. Exposed to the flame of the blowpipe, it melts on charcoal, and on cooling acquires a greyish coating. Melted with borax in a small cupel it gives a bluish-green tint to the flux, and is transformed into a red globule, which is hard enough to resist the pestle when placed in a mortar, but which is flattened out under the hammer. Melted with phosphorous salt, this alloy gives a very deep bluish-green colour to the flux, and it remains in the state of a malleable yellowish-white globule. It is easily soluble in nitric acid, even cold, leaving the gold in a spongy state, preserving the form of the specimen submitted to experiment.

Analysis gave the following results:—

Gold	0·3549
Silver	0·1194
Copper	0·5235
	0·9978

The method was as follows:—The alloy is first treated with nitric acid, leaving, as above stated, the gold in a spongy state. The silver is precipitated by a few drops of hydrochloric acid, in the form of chloride, which can be measured. A hot solution of potash precipitates

the copper is an oxide, which can be washed, dried, and weighed in its metallic state by reduction in a stream of hydrogen gas (the method of MM. Millon and Commaille). We know of no natural composition of these metals alloyed in a like proportion; gold and silver are frequently mixed together in the mineral kingdom, united together in different proportions, as is evident from numerous analyses, and especially those made by M. Boussingault; but gold ore has never been found containing more than 4 to 5 per cent. of copper. We can therefore consider it certain that the 52 per cent. of copper indicated by the analysis in the alloy above stated has been added to argentiferous gold ores by the Indian manufacturer either to give more rigidity to the metal or to increase its volume. This specimen of American archæology under notice formed part of the collection made by M. Jomard, recently purchased by M. Berthoud; it was found in the ruins in the territory of Medellin, near the Magdalen river (New Grenada); its fabrication dates from a period which it is difficult to ascertain, but it may be considered as antecedent to the conquest of America.

So wide is the field open for the different combinations of the hydrocarbons that nomenclature has become embarrassing. M. Maumené recommends a system which we place before our readers. A uniform termination for the names of these substances has for some time past been used to denote the various compounds of the hydrocarbons, *ène* in French and *en* in English. But this rule has not always been followed. Many names terminate in *yle*, and as many hydrocarbons end also in *ine* and *ol*, we have current the four terminations for substances of the same nature *en*, *yle*, *ine*, and *ol*.

It would be easy to return to the ordinary rules—that is to say, 1. To give to all the hydrocarbons names having the same termination—*en*; 2. To render them as simple as possible; 3. Not to attach the names to any theory; 4. To express as well as possible the composition of the substance.

1. Considering C_2H_2 as a molecular unity, the group or class can be represented by $C_{2n}H_{2n}$ or $(C_2H_2)_n$ in expressing the values of n by the customary words dy, tri, tetra; thus for the first group we may make use of these terms—

Monene . . .	C_2H_2
Dyene . . .	C_4H_4 or $(C_2H_2)_2$
Triene . . .	C_6H_6 or $(C_2H_2)_3$
Tetrene . . .	C_8H_8 or $(C_2H_2)_4$ &c.

2. For all the groups and classes in which the carbon dominates $C_{2n}H_{2n-x}$, the author proposes to insert between the words *mono*, *dy*, *tri*, and the termination *ene*, the letter of the alphabet corresponding by its order to the value of x—for example, to designate the hydrocarbons $C_{2n}H_{2n-6}$, he places the letter F, as being the sixth letter of the alphabet, and we have—

Monofene	=
Dyfene	=
Trifene	=
Tetrafene	$= C_8H_2$?
Pentafene	$= C_{10}H_4$
Hexafene	$= C_{12}H_6$ (benzine, benzol)
Heptafene	$= C_{14}H_8$ (toluene, toluol)

3. For the groups in which the hydrogen predominates, $C_{2n}H_{2n+x}$, the author interposes between the syllables mono, dy, &c., and the termination *en*, the word hydro, which is followed by the latter in the order of x. The result is the denoting of two groups of names very short, and, at the same time, expressive. For example, the names of the hydrocarbides, $C_{2n}H_{2n+1}$, *monohydro* ending in *ene*, and by elision—

Monhydrene	C_2H_3 (methyl)
Dihydrene	C_4H_5 (ethyl)
Trihydrene	C_6H_7 (propyl)
Tetrhydrene	C_8H_9 (butyl)

This nomenclature, so simple, is accompanied by a slight inconvenience that can be easily got rid of.

1. The names of the 8th group $C_{2n}H_{2n-7}$ in pronunciation is confounded with that of the 10th, $C_{2n}H_{2n-10}$, or

Pentagine $C_{10}H_3$, Pentagene $C_{10}H_2$.
Hexagine $C_{12}H_5$, Hexagene $C_{12}H_2$.

To remedy this, M. Maumené puts an *i*, thus—

Pentageine,
Hexageine,
Heptageine, &c.,

and thus saves the trouble of a mistaken pronunciation.

2. The names of the 3rd group $C_{2n}H_{2n}$, and those of the 9th $C_{2n}H_{2n-8}$ present a similar difficulty—

Hexene, Hexhene,
Heptene, Hepthene,

or by elision—

Hexahene,
Heptahene,
Octahene.

There is no other difficulty.

On the report of the Surgical Commission of Inquiry, and the awarding of prizes for meritorious labours, the French Photographic Society has presented a medal to MM. Jessie de Mothay et Maréchal for their process of the production of vitrified photographic images on glass, crystal, porcelain, and lava. Their processes, says the report, open a new field to photography by reproducing faithfully the very sketch of the artist. The successive employment of the iodo-cyanide and cyanide baths, which allow of a thick coating of metal to be used, which it is necessary to deposit on objects of this nature, is in itself an improvement of considerable interest. F. Moigno.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, January 17.

Professor W. A. Miller, *M.D., V.P.R.S., President, in the Chair.*

Mr. Edward J. Sparks was formally admitted a Fellow of the Society. The names of the following candidates were read for the second time, viz.:—James William Hudson, Ph.D., Principal of Trafford College, Manchester; Mr. Joseph Ince, Associate of King's College, London, 26, St. George's Place, Hyde Park Corner; and Mr. George Otley, 196, Walworth Road. For the first time were read the names of Mr. Jonathan Hearder, Plymouth; Mr. R. R. H. Davey, of the War Office; Mr. Frederick George, Cheltenham; Mr. Martin Henry Payne, 47, Mortimer Street, Cavendish Square; Mr. William Thurston Waite, 37, Jewry Street; and Mr. Henry Weston Eve, M.A., Wellington College, Wokingham.

The Secretary read a paper by Mr. T. E. Thorpe, Dalton Scholar, Manchester, "*On the Amount of Carbonic Acid contained in Sea Air.*" The author traced the history of previous researches, and referred particularly to the experiments of Lewy, who, in 1848, determined the amounts of carbonic acid and of the principal gaseous constituents in air collected over the middle of the Atlantic Ocean at different periods of the day and night. These analyses had been conducted in the eudiometric apparatus of Regnault and Reiset, which subsequent experience has shown to give fallacious results. Lewy indicated a considerable increase of carbonic acid during the daytime; in fact, the amount of this constituent was said to vary between 3·346 parts at 3 a.m., and 5·42 parts at 3 p.m., in ten thousand volumes of air under similar meteorological conditions, whilst the oxygen suffered a corresponding change from 2096 to 2106 volumes. The quantitative estimations described by Mr. Thorpe were made according to Pettenkofer's method, an aqueous solution of baryta being employed to absorb the carbonic acid from a known volume of air, the excess of baryta being ascertained by the use of a standard solution of oxalic acid. The author's

first experiments were made in the Irish Sea in August, 1865, on board the "Bahama Bank" light ship, which is situate seven miles from Douglas, Isle of Man, and consequently about equidistant from the shores of England, Scotland, and Ireland. The results and meteorological conditions are given in the form of a table, wherein it is seen that there is no perceptible variation in the amount of carbonic acid during the day and night, the hours of 4 a.m. and 4 p.m. having been selected for the observations, these times coinciding with the maximum and minimum temperatures. Similar experiments were made last year in many latitudes of the Atlantic Ocean during voyages to and from the Brazils. The results are nearly identical with the former, and the amount of carbonic acid is said to be 3·00 parts in 10,000 of air, as the general average of the whole series of seventy-seven observations.

A second part of the author's paper describes "*The Amount of Carbonic Acid contained in the Atmosphere of Tropical Brazil during the Rainy Season.*" Para was the station selected for experiment; its position on the Amazon is eighty miles from the sea. In April and May last the proportion of carbonic acid was found to be no more than 3·28 parts, whilst 4 may be quoted as the mean result for the atmosphere of Europe. The latter figure is, however, known to be often exceeded in localities not far removed from the contaminating influences of manufacturing operations and other causes.

The President proposed a vote of thanks to the author for his interesting communication.

Dr. Frankland was then invited to read a paper entitled "*Synthetical Researches on Ethers.—Part II. Action of Sodium and Isopropylic Iodide upon Ethylic Acetate,*" being a continuation of a memoir presented by himself and Mr. B. F. Duppa on a previous occasion to the Society.* The lecturer stated that two distinct classes of bodies resulted from the reactions already described—viz., 1st. Products derived from the duplication of the molecule of ethylic acetate; and 2nd. Bodies resulting from the substitution of one or more atoms of hydrogen in the methyl of acetic acid. Examples of the two classes were thus written,—

Type of Carboketonic Ethers.	Ethylic Disodacetate.
$\left\{\begin{matrix}COMe\\CR_2\\COEto\end{matrix}\right.$	CNa_2H $COEto$

Dr. Frankland then showed the mode of formation of the last-named body, and the nature of the ethylic salt resulting from the action of the iodide of an organic radical. Previous experiments had determined the results in the cases of the employment of the ethylic, methylic, and amylic iodides; the authors proceeded now to extend their investigations to the products obtained by the action of the isopropylic iodide. By the operation of sodium upon ethylic acetate, a carboketonic ether was formed, which was then digested with the isopropylic iodide employed in excess. At the end of four hours the more volatile products were distilled off by the heat of a water bath, the residual portion was acidified with dilute sulphuric acid, and again submitted to distillation. An oily liquid of agreeable odour passed over, which was a mixture of ethylic acetate, alcohol, isopropylic iodide, and two new bodies, one boiling at about 135° C., and the other when purified at 201° C. This last named substance proved on analysis to be a true carboketonic ether, to which the name *ethylic isopropacetone carbonate* is applicable. Its formation was thus accounted for,—

$$\left\{\begin{matrix}COMe\\CNaH\\COEto\end{matrix}\right. + \beta PrI = \left\{\begin{matrix}COMe\\C\beta PrH\\COEto\end{matrix}\right. + NaI.$$

Ethylic Sodacetone Carbonate. — Ethylic Isopropacetone Carbonate.

When pure, its odour might be compared with that of "damp straw in a state of incipient fermentation." It is not soluble in water, but easily miscible with ether and alcohol. Boiled with baryta this substance furnishes isopropacetone, a mobile liquid possessing a powerful camphoric odour and a burning taste. An analysis of this substance led to the formula $C_6H_{12}O$. Boiling point 114° C. It does not reduce a boiling solution of argentic nitrate, but gives the usual white crystalline body when mixed with an alkaline sulphite. Isopropacetone is considered by the authors to be isomeric with Dr. Williamson's ketone, boiling at 120° C., and also with ethyl butyral, which boils at 128° C. There were indications of the existence of a second body containing two atoms of isopropyl, but the ethylic di-isopropacetone carbonate has not yet been isolated. The other new substance, to which reference has already been made, boiled constantly at 134—135° C., and proved to be *Isopropacetic Ether*. Analysis led to the formula $C_7H_{14}O_2$, and it is consequently isomeric with ethylic valerate. From this compound the *Isopropacetic Acid* was prepared, which boiled at 175° C., and had an odour similar to that of the normal valeric acid made from amylic alcohol. It is an oily liquid, soluble to a slight extent in water, and exhibiting acid properties. The silver-salt was prepared and analysed. Its formula is—

$$C_5H_9AgO_2 = \left\{\begin{matrix}C\beta PrH_2\\COAgO.\end{matrix}\right.$$

The constitution of the new bodies is shown in the author's paper by the aid of graphic formulæ, and the existence of a third member of this group of isomeric acids is already ascertained, and will form the subject of a separate communication to the Society. It is the *Trimethacetic Acid*, having the formula—

$$\begin{matrix}CMe_3\\COHo.\end{matrix}$$

Dr. Frankland proceeded, finally, to institute a comparison between the properties of isopropacetic and valeric acids, which are identical in all respects save one—viz., the power which the latter possesses in common with its ether of rotating a beam of circularly polarised light—a physical difference which fully bears out the authors' theoretical assumptions based upon their different synthesis.

A few remarks by Drs. Debus and Odling followed the reading of the paper, and the President proposed a vote of thanks to Professor Frankland and Mr. Duppa for their interesting communication.

Professor J. A. Wanklyn then gave an account of a new mode of analysis in a paper entitled "*Titration of the Compound Ethers.*" After referring to the unsatisfactory nature of the indications afforded by the combustion of the compound ethers as a guarantee of purity, Professor Wanklyn described a very expeditious and accurate mode of titrating them. Known quantities of the ether and of alcoholic potash were heated in a sealed tube, and the excess of alkali remaining was afterwards determined by a standard solution of sulphuric acid, the last stage of visible blue tint in the litmus serving as the point of saturation. A number of examples were given in illustration of the accuracy of the method. Thus, 100 parts of benzoate of ethyl, when saponified, should yield theoretically benzoic acid capable of saturating 26·06 parts of potassium. The numbers found by experiment were 25·77 and 25·78.

The President having elicited some further particulars indicative of the rapidity with which these experiments could be conducted,

Dr. Williamson said he considered the method now proposed by Professor Wanklyn would be likely to prove of great value, since the results of the ultimate analysis of these ethers were altogether unsatisfactory, and he thought it desirable to endeavour to extend the principle to the examination of other classes of bodies.

A paper on "*Quantitative Analysis by Limited Oxida-*

* *Jour. Chem. Soc.*, vol. xix., p. 395.

tion. Examples: Lactic and Diethoxalic Acids," by Messrs. Ernest T. Chapman and Miles H. Smith, was read by the first-named gentleman. The authors referred to a previous paper (Chapman and Thorp, *Journal Chem. Soc.*, December, 1866), in which it was distinctly proved that the normal acids of acetic series are not attacked by dilute chromic acid. It was also shown that these acids resist attack, even in the nascent state. From this observation it follows that all the carbon of alcohol, for instance, may be obtained in the form of acetic acid. The authors have oxidised the lactic and diethoxalic acids with a ten per cent. solution of bi-chromate of potash, containing just enough sulphuric acid to produce chrome alum if all the chromic acid were reduced. Lactic acid, as is well known, yields, when oxidised with binoxide of manganese and sulphuric acid, aldehyde and carbonic acid. With the bichromate solution the same results are obtained. The authors, having carefully determined the amount of carbonic acid liberated, find that almost exactly one-third of the carbon passes off in this form, thus proving the equation:—

$$\left.\begin{matrix}\mathrm{CMeHHIo}\\ \mathrm{COIo}\end{matrix}\right\} + \mathrm{O} = \mathrm{CMeHo} + \mathrm{H_2O} + \mathrm{CO_2}.$$

Lactic acid. Aldehyde.

They also determined the amount of acetic acid formed from a known weight of lactic acid, which, converted into barium salt, proved to be within one or two-tenths per cent. of the quantity required on the assumption that one equivalent of lactic acid yields one equivalent of acetic acid. The authors find that diethoxalic acid (the acid obtained by Frankland and Duppa by the action of zinc-ethyl on oxalic ether) when treated with the above oxidising mixture splits up with the greatest ease into carbonic acid and propione. The former was accurately determined, and found to correspond to one-sixth of the total amount of carbon in the compound. The propione also was determined. This was effected by operating in an atmosphere of carbonic acid, and subsequently absorbing this gas by potash, by which device all loss from effusion is avoided. The result of this operation was that the amount of propione obtained was within 0·6 per cent. of that demanded by theory. This was said to be the only instance on record of a volatile liquid having been determined with quantitative accuracy. These facts prove the following equation:—

$$\left.\begin{matrix}\mathrm{CEt_2HIo}\\ \mathrm{COIIo}\end{matrix}\right\} + \mathrm{O} = \mathrm{CEt_2O} + \mathrm{H_2O} + \mathrm{CO_2}$$

Diethoxalic acid. Propione.

The propione was in its turn oxidised and made to yield acetic and propionic acids, which together amounted to 99·3 per cent. of the theoretical quantity.

The proportion of oxygen required to convert the propione into these acids was then determined, and found to correspond to three equivalents. This result was arrived at by precipitating the sesqui-oxide of chromium reduced by a given weight of propione. From the foregoing statement it appears that the following equation is true:—

$$\mathrm{CEt_2O} + \mathrm{O_3} = \mathrm{C_2H_4O_2} + \mathrm{C_3H_6O_2}.$$

Propione. Acetic acid. Propionic acid.

Finally, the authors state that quantitative analysis of many, perhaps most organic compounds can be effected by limited oxidation, and not only should we then learn the total amount of carbon, but also the form in which it exists in the compound under examination. The results obtained in the analysis of diethoxalic acid come out as sharply as in the best combustions.

Mr. Chapman exhibited the apparatus made use of in these experiments, and showed a sealed tube containing equal weights of glacial acetic acid and crystallised chromic acid, which had been heated for a period of four hours in a water bath, without perceptible change or alteration of colour.

The Secretary read a paper "*On the Preparation of Berberine from Coscinium fenestratum,*" by John Stenhouse, LL.D., F.R.S. The plant in question is a large rope vine growing in the forests of Ceylon and other parts of India. It is met with in commerce under the name of "Colombo wood," and berberine has already been extracted from it by Mr. J. D. Perrins. The author obtains a larger yield of pure berberine, from 2 to 3½ per cent., by exhausting the groundwood with subacetate of lead solution instead of plain water. Part of the alkaloid separates out on cooling; but a further quantity is obtained on adding an excess of nitric acid to the supernatant liquid. Lime or ammonia may then be used to decompose the nitrate, and the impure berberine resulting may be further treated, as described in the author's paper, for the purpose of effecting its complete purification. Dr. Stenhouse recommends the adoption of the same process for the extraction of theine from tea.

Another paper by Dr. Stenhouse stands over to be read at the next meeting; it is entitled "*Note of some Varieties of Orchella Weed, and Products obtained from them.*" Also a paper by Dr. T. L. Phipson, "*On the Eggs of Corixa mercenaria.*" At a late hour the meeting was adjourned until February 7.

ROYAL INSTITUTION OF GREAT BRITAIN.

On Friday evening, Dr. Tyndall delivered a lecture at the Royal Institution, "*On Sounding and Sensitive Flames.*" Commencing with the history of the subject, the lecturer stated he believed Dr. Higgins first noticed the sounding of a hydrogen flame when enclosed in a glass tube; and with regard to the second part of the subject—sensitive flames—that the jumping of a naked fish-tail flame in response to musical sounds was first noticed by Professor Lecomte. He made the important discovery that the flame did not jump until near flaring.

In the first experiment, in which a candle was moved rapidly through the air, a fluttering noise was produced, and a continuous band of light, slightly indented, or raised a little at the extremities, was visible. Blowing against a candle caused a similar fluttering sound, indicative, as in the preceding case, of a rythmic action. When a fluttering of the air is caused at the embouchure of an organ-pipe, the resonance of the pipe reinforces that particular pulse of the flutter whose period of vibration coincides with its own and raises it to a musical sound. Dr. Tyndall blew into the embouchure, and obtained a musical note from an organ-pipe in this way. When a gas-flame is introduced into an open glass tube, the sound is produced in the same manner. The pitch was shown to be dependent upon the length of the tube, by using tubes of various lengths.

The fact that the vibrations of the flame consisted of partial extinctions and revivals was beautifully illustrated by throwing an image of the flame on to a screen by means of a concave mirror; when the current of air which produced the fluttering was stopped, a continuous band of light was produced by moving the mirror; when the flame was vibrating the image projected consisted of a chain of luminous spots. The possibility of making the vibrations of a singing flame start a silent flame was shown thus:—Two flames were enclosed in glass tubes which had cardboard sliding tubes, by which the length of the tube could be altered; one flame was made to sound by adjusting the length of the tube, and the vibration of this speedily caused the other to sound, which up to that time had been silent. Both flames must be so nearly in unison as to produce distinct beats. The sound of a flame in a glass tube was changed markedly by a membrane cover being placed upon the tube. Afterwards a fishtail burner was brought over the same tube, the broad side of the flame being at right angles to the axis of the tube; it immediately emitted a note of the same pitch as that of the sounding flame in the tube, but of peculiar tone—in fact, the same as that produced by the membrane in the previous experiment. Blows upon

the anvil, whistling, and other methods of causing vibrations to be communicated to the air, were shown to have no effect upon an ordinary candle-flame, but upon distorting it by means of a blowpipe, it jumped upon blowing a whistle. By the position in which the blowpipe was placed with regard to a fishtail flame, the latter was cut in two; when in this condition it became altered in shape by the sound of the whistle.

In the next experiment a bat's-wing flame was used, which was not at all affected at first, but by increasing the pressure of gas it became very sensitive, and shot up a number of forks each time the whistle was sounded; it was similarly affected by a blow upon the anvil from a hammer. Two flames, the one short and forked, the other long and straight, exactly interchanged their character upon a whistle being blown. Dr. Tyndall explained that the apathy or sensitiveness of these flames depended upon the pressure of gas; and to have the pressure at his command the gas was supplied from a small gas-holder in the lecture theatre. The flames were clearly shown to be scarcely affected by low tones; one flame of nearly 20 inches long was of marvellous sensibility, a tap on a distant anvil knocking it down to 8 inches. Tuning forks of low pitch had no effect whatever upon it, but it immediately responded to the overnotes of the forks. Similarly the blow of a hammer upon the table had no effect upon a flame, while a blow upon the anvil immediately affected it. Illustrative of the same fact, an inverted bell was made to vibrate, and produced a loud deep tone. No effect was produced upon the flame, but a coin brought in contact with the vibrating metal raised the pitch, and the flame, previously twenty inches long, fell, and re-ascended immediately. The human voice evidently affected it, some sounds more particularly. The sound of the vowel U had no effect upon the flame; O scarcely any, while E affected it strongly; the sound "Ah!" was immediately responded to by the flame. Dr. Tyndall recited a few lines from Spenser, in which particular words attacked the flame markedly. The winding up of clockwork, little jets of compressed air issuing from a small orifice, and a "hiss," all affected the flame so rapidly that we could not detect the interval of time between the sound and its effect. These last sounds were made in the gallery by Dr. Tyndall's assistant. The lecturer stated that the rustling of a lady's dress drove the flame frantic; and it was very evident during the lecture that the occasional whispering of the audience affected it powerfully.

ACADEMY OF SCIENCES.

January 21, 1867.

(From our own Correspondent.)

M. Le Verrier requested the insertion in the *Transactions* of the Academy of some notes relative to examinations of the eruptions of Vesuvius, and the newly sprung-up isles of Santorin, made by M. Fouqué, well known by his observations and studies thereon; also his experimental researches on the indices of refraction of saline solutions. His aim was to ascertain whether the law as laid down by Biot and Arago relative to gaseous mixtures was equally true for liquids. Having made experiments upon 153 solutions, he came to the following conclusions, giving, at different temperatures for each body, its chemical composition, specific gravity, and index of refraction:—

The number representing the index of refraction varies according to the temperature. From 50° F. to 203° F., this variation often attains the hundredth part, and is greater in proportion as the liquor is the more concentrated. Its refringent power diminishes when the temperature is increased, and this diminution from 50° F. to 203° F. is about the thousandth part of the original size. The dispersion diminishes also with the temperature. In the same interval the distance between the two lines A and B of the spectrum can present a difference of a thousandth part. The law of Biot and Arago, that the index of a mixture of two gases is the mean between that of the two elements which constitute it, is not strictly true in the case of its application to liquid mixtures; yet, however, it may be regarded as a very close approximation, differing little from the truth, for a great number of saline solutions.

"The Academy is already aware," said M. Coste, in a communication made on the 21st, "by communications made by several naturalists, that I have organised at Concarneau, with the co-operation of Mr. Gerbe, and the master pilot Guillon, an observatory of the inhabitants of the ocean, which is one of the most interesting innovations of modern times. There, in a reservoir 1794 square yards in extent, and 10 feet deep, divided into six compartments, hollowed out of solid granite, and defended by thick walls against the violence of the waves, we have succeeded, by means of sluice gratings that can be opened and shut at will, in imitating so well the flux and reflux of the tide that the most concealed organic phenomena of the deep are accomplished under the eyes of the observer. Not only do the greater portion of the species live there in a state of complete domestication, exhibiting their habits of life, but they carry on their reproduction, and offer a new field of inquiry to the embryogenist. We cite a few examples." The master pilot, Guillon, wrote to M. Coste that at the beginning of April, 1866, he had placed a couple of the small species of *Squalus Catulus* (Linn.) in one of the compartments of the aquarium. The female laid eight eggs during the month. These were hatched in the commencement of December. The incubation therefore lasted about nine months. The young animals are thriving. Thus, a phenomenon of the most delicate organisation was accomplished artificially with as much regularity as if it had taken place in the great deep. This is, in the opinion of M. Coste, one of the great decisive proofs of the perfection of the vast hydraulic apparatus in which he makes his experiments; thanks to this perfection, the reproductive process can be watched from day to day, from hour to hour, as well as that of a fowl from the very egg. There is also an aquarium in an adjoining building, furnished also with all appliances for closer examination, dissections, lecture-rooms, &c. In this laboratory, M. Coste offers a generous hospitality to all friends of science, and in it are drawn up all the regulations relative to the fishing laws.

M. Leverrier took up the discussion, raised by him on the 17th inst., at the monthly meetings of the Scientific Association of France, relative to the shower of falling stars during the month of November. His theory, or rather, properly so to speak, his hypothesis, is in strict analogy with that of Sr. Sciaparelli. At an early date, that is to say before the year 126 of the Christian era, these nebulous masses were of a spherical, or some other shape. At that period Uranus caused them to go out of their path, partly or wholly, and describe an elongated orbit, which brings them within reach of the attraction of the earth. The major axis of this ellipse is equal to about 70 diameters of the earth. In $33\frac{1}{4}$ years the cluster performs the revolution of its orbit, and its length is such that it occupies such a space that the duration of its perihelion passage is more than a year. M. Leverrier does not affirm the creation of the falling star clusters of November, but he demonstrates the possibility by comparing the principal positions and elements of the orbits of the nebulous masses, and of Uranus at the period of the year 126·212 of our era.

Gold Amalgam.—Three pounds of amalgam, from which the liquid metal has been carefully pressed out, will yield one pound of gold. The gold remaining after the quicksilver has been driven off by the heat from the amalgam is a porous mass, somewhat resembling sponge cake in appearance.—*Hittel's Resources of California.*

NOTICES OF BOOKS.

Intensity Coils; How Made and How Used. By "Dyer." London: Suter, Alexander, and Co.

The induction coil has now come into such general favour and is used for such varied purposes, as a medical instrument, a means of scientific research, and an amusing toy for winter's evenings, that several treatises have lately appeared, describing the best methods for its manufacture and management. The object of the little work before us is explained in the following manner in the preface:—

"What is an intensity coil? How does it differ from other coils? How is it made? What will it do? These and similar questions are being continually asked, and to furnish intelligible replies to them the following pages have been written.

"It is not a scientific treatise that is here offered to the public, but simply the necessary instructions that those who want to make or use intensity coils desire to obtain."

For these purposes the writer gives a short abstract of all the important electrical laws that are connected with his subject, and the general characteristics of dynamic and current electricity; having done which he proceeds to state the best manner of forming a tolerably powerful coil, concluding with a list of the experiments that may be performed with it when made. The following notes on the manufacture of the coil show some of the principal precautions necessary to be taken to insure perfect insulation:—

"The primary wire consists of copper wire covered with cotton or silk, and of a size known as No. 15 or No. 16, averaging about 18 to 20 yards to the pound. One end of the wire is to be passed from the inside through one of the holes in the reel end, and then carefully wound over the cylinder up to the other end, and then back again, so as to form two layers of wire one over the other.

"When the primary wire is laid on, it should be varnished with two or three successive coats of varnish composed of shellac dissolved in spirits of wine. Care should be taken that one coat be thoroughly dry before a second is put on. The varnish should be thin, so that it may be readily absorbed by the covering of the wire and conveyed to the underneath layer."

The secondary wire "is also formed of copper wire, but it must be covered with silk, and of a size known as No. 39, averaging about 100 yards to the ounce; the quantity required will be about 800 yards. In winding this wire on the reel the most scrupulous care is needed, not only to avoid any break in the wire, but also any kink or bend in it. One layer of wire is to be laid on at one time, and then most carefully varnished with shellac varnish, and when dry covered with four or five layers of gutta-percha tissue."

Any one possessed of a slight amount of mechanical skill would find no difficulty in the construction of a coil with the assistance of the directions given in this work. The many, therefore, who would prefer to construct their own instruments rather than purchase them will welcome this book as a valuable auxiliary, and will suffice to insure its success.

CONTEMPORARY SCIENTIFIC PRESS.

[Under this heading it is intended to give the titles of all the chemical papers which are published in the principal scientific periodicals of the Continent. Articles which are merely reprints or abstracts of papers already noticed will be omitted. Abstracts of the more important papers here announced will appear in future numbers of the Chemical News.]

Sitzungsberichte der Kaiserlichen Akademie der Wissenschaften (Mathematical and Natural History Section).

July, 1866.—Ad. Weiss: "*Researches on the History of the Development of Colouring Matter in the Vegetable Cells.*"—Unger: "*Short Notice on the Fossil Wood from Abyssinia.*"—Ischermak "*On Sulphide of Silver* (Silberkies)."

Jahrbuch der Kaiserlich-Königlichen Geologischen Reichsanstalt.

No. 3, 1866, July, to and inclusive September.—"*The South-West End of the Trachytic Formation of the Region of Schemnitz-Kremnitz,*" by von Adrian, with numerous and valuable Mineralogical Analyses, by von Sommaruga and others.—"*Scientific Researches in the Laboratory:* (a) *Four Analyses of Divers Varieties of Basalt,*" by von Sommaruga; (b) "*Analysis of Melaphyr,*" by the Same; (c) "*Analysis of Badeschlamm*—i.e., *Mud Deposited from a Natural Spring;*" (d) "*Analysis of Braunkohle occurring in Carynthia;*" (e) "*Hydraulic Lime from Nadworna;*" (f) "*Analysis of English and Bilin Emery;*" (g) "*Analysis of Braunkohle from Ghymes, Hungary.*"

CORRESPONDENCE.

Commercial Analyses.

To the Editor of the Chemical News.

Sir,—I did not know that analysts were classified as "high" or "low" till I read your correspondent's letter in No. 370; but the following analysis was evidently made by a member of the latter division. Certainly either the fee or the work is too low; yet he has written a book and has initials to his name. Let us hope he is the only "low" person known at Burlington House.

I am, &c. N. D.

Analysis of a Sample of Superphosphate.

Moisture	12·42
Water of combination, with a little organic matter (containing nitrogen ·25; equal to ammonia ·30)	12·05
Biphosphate of lime (equal to bone-earth made soluble 13·03)	8·35
Insoluble phosphates	16·64
Sulphate of lime	34·52
Alkaline salts	10·82
Insoluble earthy matters	5·20
	100·00

Fee, 1*l.* 1s.

The Use of Gun Cotton in Blasting.

To the Editor of the Chemical News.

Sir,—A letter appeared in your impression of January 4, in which our name was coupled with the manufacture of gun cotton, and as the remarks there made are somewhat calculated to injure us, we trust you will allow us a short space for an explanation.

The description given by your correspondent as to the best mode of using this material is correct so far as it describes the ordinary operations of the miner when blasting with powder, the conditions under which this well-known compound can be used being identical with those required for gun cotton, our object having been so to arrange our manufacture that the employment of the two materials should assimilate as much as possible; but here the correctness of the description ends. Gun cotton is in every respect as safe, many report it safer than powder; one great danger of the latter, viz., its liability to leave grains adhering to the sides of the hole upon which friction from the tamping rod is constantly taking place, is altogether removed, the cotton goes in a mass to the bottom of the hole, and no residue forming a train by which the entire charge is exploded ever remains.

The experience of your correspondent as to results is so opposed to our own and to that of a large number of consumers, as notified to us by their letters, that we have no hesitation in saying the trials have not been properly made. In using more than one length of cotton the fuse should not be carried through the whole of the charges, such an arrangement being likely to prevent the simultaneous ignition of the pieces, thus retarding the combustion and diminishing the effect; and this was undoubtedly the cause of the poor result obtained by your correspondent. Properly applied, the cost of gun cotton (tested by the work done) is less than that of powder.

We have lately prepared a very condensed charge, one inch of which will be found equal to six inches of powder. Of our $1\frac{1}{4}$-inch diameter, five inches in length are equivalent to one pound of powder, and can be supplied for $4\frac{1}{2}$d. By the use of this in hard granite rock, a large saving in boring is effected; the charges slip readily into the hole, leave no residue on the side, and only require to have the fuse connected with the uppermost piece; the total absence of smoke, comparative freedom from danger, portability and convenience of form, combined with the saving in labour and material, are advantages which are bringing gun cotton largely into use, and are thoroughly appreciated by those workmen who, by a proper and judicious application, have reaped the full benefit to be derived from it. Thomas Prentice & Co.

173, Fenchurch Street, London, E.C.

Organic Matter in Water.

To the Editor of the Chemical News.

Sir,—Having observed no reply to your correspondent "B. J. G.," in your impression for Dec. 28, 1866, I would suggest to him the following method of determining the character and origin of the organic matter in waters. If not theoretically perfect, it possesses a practical value, and is no doubt substantially identical with that in use by Dr. Letheby. It depends upon the fact that animal matters of the kind which find their way to the sources of drinking water may be regarded as invariably containing nitrogen, and as yielding by their decomposition one of the two nitrogenised bodies, ammonia and nitric acid, which are sufficiently easy of detection. Hence, if a water be found to exercise a palpable deoxidising action upon permanganate of potash solution, which cannot be explained by the presence of any inorganic constituent (such as the protosalts of iron, &c.), and at the same time is free from both the above-mentioned bodies, the inference is inevitable that organic matter—not of animal, and therefore of vegetable origin—exists in the water. As regards the formation of these two compounds in waters subject to animal pollution, it appears highly probable that the action is successive, an early result of the breaking up of the chemically complex animal substance with simpler forms being ammonia, while nitric acid is produced by the gradual oxidation of the latter; a reaction analogous to that exhibited in the common lecture experiment, where a spiral of platinum wire is retained in a state of ignition by the heat resulting from the oxidation of gaseous ammonia, orange fumes of pernitric oxide appearing in the vicinity of the wire. Such, indeed, is most probably the history of the nitre obtained from the nitre beds, and hence of nearly all the nitric acid of commerce. If the theories above stated be well founded, it is evident that highly important conclusions may be drawn from the presence of ammonia and nitric acid in waters. Thus, if we find ammonia alone, we may infer that the animal contamination is of recent standing; while the detection of nitric acid also would imply that sufficient time had elapsed since the first infiltration of foul matters for the oxidation of the ammonia. Again, if nitric acid, and no ammonia be found, we may assume that the impurity of the water is of a temporary or intermittent character, and that its pollution had ceased some little time before the specimen examined was drawn. Each of these cases has been met with in practice by the writer. With respect to the estimations of organic matter by permanganate of potash given by Dr. Letheby in his accounts of the metropolitan waters, he seems to make use of the beautiful system lately brought before the Chemical Society by Dr. W. A. Miller, the organic matter being apparently expressed in terms of crystallised oxalic acid, the substance used by that chemist for the titration of the permanganate solution.

I am, &c.

Thos. P. Blunt, B.A., F.C.S.

Shrewsbury.

MISCELLANEOUS.

Graphitic Boron.—Professor Wöhler informs us that the February number of the *Annalen* will contain a notice of a further examination which he has made upon the copper-coloured, tabular, hexagonal crystals discovered by M. Deville and himself, and supposed to be graphitic boron. This is now proved to be a combination of boron and aluminium, AlB_2.

New Filtering Apparatus.—An economic filter and percolator has been devised by Mr. F. W. Hart. By an ingenious combination of syphon-tube and filtering medium, any test liquid may be drawn from a bottle in a state of limpidity, and, if necessary, returned again turbid to the stock for refiltration. By slight modifications the apparatus is used for filtering alcoholic ethereal or caustic alkaline solutions out of contact with the air, and it can be adapted to a water bath so as to admit of the filtration of gelatinous liquids. The apparatus is specially contrived for use amongst photographers, but it is evident that there are many uses in chemical, pharmaceutical, and manufacturing laboratories to which this apparatus can be economically applied.

Conduction of Sound by Hydrogen and Air.—Professor Tyndall, in his first lecture on "Vibratory Motion," delivered at the Royal Institution on Tuesday last, showed a novel experiment, illustrating the very low conductivity which hydrogen possesses for sonorous vibrations. A bell, struck by clockwork, was placed under the receiver of an air pump, and the air exhausted as perfectly as possible. It was stated that by applying the ear close to the glass a faint sound could still be heard. The exhausted receiver was then filled with hydrogen, when the bell was again heard to sound, although faintly. On pumping out the hydrogen all trace of sound entirely disappeared, even though the ear were placed close to the receiver. Hydrogen being about fifteen times lighter than air, it might be considered that sound would travel in an atmosphere of hydrogen as readily as it would in air exhausted to two inches barometric pressure. But on trying the experiment it was found that when two inches of air were passed into the receiver, it allowed far more sound of the bell to pass through it than did the full atmosphere of hydrogen, showing that conductivity for sound depended upon something more than mere density. It was then shown that sound travelled with almost the same ease through air exhausted to half its normal density that it did at the ordinary pressure.

The Chemists' Ball.—A ball will be held at Willis's Rooms, King Street, St. James's, on Wednesday next, January 30, under the patronage and support of the leading members of the trade, the surplus of which will be given to the Benevolent Fund of the Pharmaceutical Society. The following gentlemen have already consented to become stewards:—W. R. Barker, Esq., James Bass, Esq., W. H. Bell, Esq., Robt. Bentley, F.L.S., J. Bourdas, Esq., Elias Bremridge, Esq., Chas. Croydon, Esq., Robt. Curtis, Esq., Edward Harvey, Esq., A. Hinton, Esq., Theophilus Redwood, Ph.D., C. H. Savory, Esq., W. A. Tilden, Esq., A. C. Trotman, Esq., R. S. Starkie, Esq., and R. B. Warwick, Esq. Application for tickets to be made to the following stewards, who form the committee:—Dr. John Attfield, 18, Beacon Hill, N.; Mr. Thomas Billing, 143, New Bond Street, W.; Mr. Richd. Forrest, 81, Hatton Garden, E.C.; Mr. G. J. Haddock, 338, Oxford Street, W.; Mr. S. A. Letts, 89, Long Acre, W.C.; Mr. T. D. Watson, 18a, Basinghall Street, E.C.; Mr. Henry Smith, Honorary Secretary, 37, Wigmore Street, W. Tickets, including supper, wine, and refreshments during the evening, lady's, 10s. 6d., gentleman's, 15s. Coote and Tinney's band will be in attendance. It gives us great pleasure to draw attention to the above. No pains have been spared to make the gathering thoroughly respectable. Each ticket is countersigned by a steward, who is responsible for the holder, and tickets are only issued to persons who are in some way known to those who have undertaken the management of the affair. It promises to be very successful, and it is to be hoped that it will be the first of an annual series. With a conference in the summer and a ball in the winter, something must be done towards breaking down exclusiveness and jealousy, and establishing a kindly feeling amongst those following a common calling.

Meetings for the Week.

Monday, January 28.

Medical Society, 8 p.m.

Tuesday, January 29.

Royal Institution, 3 p.m. Professor Tyndall, F.R.S., "*On Vibratory Motion, with special reference to Sound.*"

Wednesday, January 30.

Society of Arts, 8 p.m.

Thursday, January 31.

Royal Society, 8½ p.m.

Royal Institution, 3 p.m. Professor Tyndall, F.R.S., "*On Vibratory Motion, with special reference to Sound.*"

Friday, February 1.

Royal Institution, at 8 p.m. J. Scott Russell, Esq., F.R.S., "*On the Crystal Palace Fire.*"

Saturday, February 2.

Royal Institution, at 3 p.m. G. A. Macfarren, Esq., "*On Harmony.*"

ANSWERS TO CORRESPONDENTS.

Vol. XIV. of the Chemical News, containing a copious Index, is now ready, price 11s. 6d., by post, 11s. 6d., handsomely bound in cloth, gold-lettered. The cases for binding may be obtained at our Office, price 1s. 6d. Subscribers may have their copies bound for 2s. 6d. if sent to our Office, or, if accompanied by a cloth case, for 1s. Vols. I., II., and VII. are out of print. All the others are kept in stock. Vol. XV. commenced January 4, and will be complete in 26 numbers.

*** In publishing letters from our Correspondents we do not thereby adopt the views of the writers. Our intention to give both sides of a question will frequently oblige us to publish opinions with which we do not agree.

X.—It was an oversight. The review has not yet appeared.

T. R. O.—The processes directly. The tables when ready. No biographical notice has been published in England.

F. C. S.—The attempt to induce crystallisation of the fused glycerin by the introduction of a fragment of solid glycerin was made, but without success.

T. Jones.—Dissolve standard silver in nitric acid, evaporate, and fuse. Then dissolve in ammoniacal water, and add sulphite of ammonia. On heating, pure silver will be precipitated. Wash this, and dissolve it in nitric acid, evaporate to dryness, fuse, and recrystallise. The product will be pure nitrate of silver.

Phosphide of Magnesium.—We have received a letter from Mr. Thomas P. Blunt, of Shrewsbury, containing an account of further experiments on the phosphide of magnesium, but as they are at present incomplete, and the author has not yet had an opportunity of meeting the charges of inaccuracy brought against him by Mr. Parkinson, the further discussion of the subject must necessarily stand over until the appearance of the forthcoming *Journal of the Chemical Society*, which will no doubt contain the official report of Mr. Parkinson's statements at the meeting of the 6th ult.

Analyses of Phosphates.—A correspondent writes:—"I could mention some awkward facts as to these determinations; perhaps more where five guineas have been paid than where 10s. 6d. or 21s. I have had superphosphates, which could not contain over 30 per cent. total phosphates, and perhaps of this 24 per cent. or 25 per cent. soluble, certified, to my great astonishment, 30 per cent. soluble, and total 34 per cent. Can you wonder if my partner, who is not a chemist, hunts up a '*high*' analyst who is a great authority amongst agricultural clubs, and parades his analysis of 30 per cent. soluble, in preference to one who only gives 25 per cent., the samples being identical in every way?"

Ansell's Fire-damp Indicator.—Mr. Ansell has drawn our attention to a slight error which appeared in our "Answers to Correspondents" for January 4. It was there stated that a full account of the "Indicator," *written by Mr. Ansell himself*, appeared in the Chemical News, vol. xii., p. 280. The article in question was, however, written by Mr. McLeod, and contained many well-merited compliments to Mr. Ansell. This gentleman is, therefore, anxious to disclaim the authorship of expressions which, although they might justly and gracefully be applied to an inventor by an impartial writer, would confer no honour if written by the discoverer himself.

E.K.—The word *teratomic*, which has puzzled you in the "Dictionary of Science," is evidently a misprint for *tetratomic*. The mixing up of Latin and Greek is therefore only apparent. You can have no better book for initiating you in the mysteries of modern chemistry and nomenclature than Dr. A. Wurtz's "Introduction to Chemical Philosophy" advertised in our pages. The temperatures you quote are certainly very low. But was the thermometer trustworthy?

Received.—"A New Chemical Nomenclature," by T. D. Tillman, A.M., New York.

LONDON WATER: PAST, PRESENT, FUTURE.

PRESENT.

Many eminent observers have come to the conclusion that evil effects follow the use of the London water, and notably, according to some, in the production of cholera. This has been inferred from the limited area where the epidemic of 1866 raged at first, being supplied by one London company, and the area was mapped out as being bounded by the supply of this water. But never more than now has water-supply as a cause of epidemic disease been in less favour than at present. These diseases are almost without exception most fatal among the lowest classes, and amongst these the care of separating sewage emanations from the water supply is least provided against. In a district where an epidemic is raging, foul cisterns or butts, without exception, will be found for the storage of water, sometimes for thirty-six hours (from deficiency as regards quantity), communicating with the storage for sewage by a waste-pipe without tap or syphon. Poison is in the sewage, and there is a direct communication between the sewage and water, from defect of local appliances, and where one house is so supplied, the whole street built on the same plan will be only a repetition of the copy.

But it is absurd to compare local defects of supply and storage with chemical analyses made at the spot whence the water is supplied. The evidence of the chemists before quoted shows that the purer the water the more readily will it carry poisonous matters, from the inorganic matters in the water being in a slight degree disinfectant. If, then, with the present water service, at once for sewerage and house supply, an impure water could prove such a fatal vehicle, what would have been the state of affairs if pure soft water had been used? Of course the general introduction of sewage into water must be guarded against, but the local causes, acting in a very limited area, are infinitely more important, from greater concentration and smaller means of oxidation. In a word, do not let us confuse the quality of water as supplied from the filtering beds with that which is actually in household use; let the chemical and engineering bearings of the subject be always carefully separated, and we shall in all probability find, if the water be drunk as it is supplied from the filtering beds, that, except on the score of hardness, the present London water is as wholesome as chemical analysis has proved it to be.

The chemical means of rendering the London water still better, as lately suggested, have more interest when discussed in relation to the future. No one has asserted that the Thames water had anything to do with the late epidemic, and its water is inferior to that from the Lea. The sewage tidal reflux does not probably reach the water, when it is obtained for drinking purposes, in any case; but that from towns on the banks of rivers above such sources would be less thoroughly oxidised in a small stream than a large one. Sir Benjamin Brodie has expressed his conviction that the noxious quality imparted to the Thames water by the sewage of Oxford is not removed by the time this water reaches Teddington Lock. If this were so, the River Lea must be in a dangerous state. But we maintain that such matters should be disinfected by natural and rational means, and their introduction for the future should be provided against. We cannot think that such matters, if present, could escape detection by the present accurate use of potassic permanganate, however fallacious its use may sometimes be. The quantity of oxidisable matter at present in the London water cannot be compared with that existing in 1851, from the fact that the means of testing for it have only lately been applied. The colour of the water has certainly been improved by filtration, but the temperature is still very variable. It has been shown that the Thames supply is almost inexhaustible, and the only reason for its abandonment urged by the Commissioners was the introduction of sewage, which now is being yearly diminished in quantity. The applicability of river water, then, turns upon the sewage question, and on this account the Thames water is a good source for supply, if it be properly used, and there certainly is no reason for smaller and more dangerous streams to be pressed into service while it exists.

SCIENCE AND FIRE-DAMP.

The sciences of chemistry and physics have of late years been so fully under the control of reason, have admitted of such easy application, and made such steady progress, that the public generally look to the masters of them for remedies against evils that continually are arising, whether under an old or a fresh form; and timely remedies have been so often thus supplied, dangers and difficulties have been so successfully, because rationally, met, that it almost seems, with our present amount of knowledge—however imperfect it may be—that a difficulty has only to arise for it to be thoroughly subdued. Numerous colliery accidents that have occurred recently, both in England and on the Continent, arrest, by the wholesale loss of life attendant upon them, the interest of all. A remedy easy of application against any more such has come to be considered as a necessity. In answer to this appeal, M. Somonet, a pupil of M. Austry, proposed to the Academy of Sciences (Jan. 14, 1867) the introduction into all drifts of electrical conducting wires, so that the inflammable gases may be set on fire by interrupting the electric circuit before time has been given for them to collect in dangerous quantity. The plan appears very feasible and simple, and we hope that the suggestion may meet with some notice.

The full import of such a suggestion can hardly yet be appreciated, but it serves as one of the best examples of modern times to show how useful applications fall readily and almost infallibly from researches in the first place of abstract and theoretical value only. Let us not, then, undervalue the powers of theory, but remember with Liebig, that "we value facts because of their permanence and immutability, and because they supply the grounds for ideas; but a fact acquires its true and full value only through the idea which is developed from it."

An Extraordinary Medical Bill.—At the Commissioners' meeting at Cheltenham lately, a letter was read from Mr. Horsley, county analyst, asking for the payment of the sum of three guineas for poisoning sixty-three dogs in the months of July and August for the Commissioners, and by order of the police. It was resolved that, as the police ordered the execution, they should pay the account.—*British Medical Journal.*

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On the Preparation of Pure Silver, by Professor* J. S. Stas.

(*Concluded from page 27.*)

Second Method.—This method furnishes it easily and more promptly than any other known way; it has the special advantage of giving it in a state of rare purity. I will describe it in detail, as I am convinced that it would be useful in laboratories and in the workshops of the Mint for the preparation of assay metal or *standard* silver.

It is based upon the *complete* reduction which ammoniacal solutions of silver compounds undergo when added to ammoniacal cuprous sulphite, or to a mixture of sulphite of ammonium and any ammoniacal salt of copper.

At the ordinary temperature this reduction takes place slowly with deposition of black, blue, or grey silver, according to the dilution of the liquids. Above a temperature of 60° C. the reduction is almost instantaneous, and the silver is precipitated in a state of division corresponding to the dilution of the liquid; its colour varying from grey to pure white.

This is how I prepared silver by this method.

Silver coin is dissolved in dilute and boiling nitric acid; the solution of nitrate of silver and of copper is evaporated to dryness, and the saline mass fused. This fusion is necessary to destroy the *nitrate of platinum, which is often formed in dissolving silver coin.*†

After cooling, the nitrates are taken up by an excess of ammoniacal water. The ammoniacal solution is left to rest *for forty eight hours.* The limpid liquid is filtered through a double filter of paper, and then diluted with distilled water until it contains no more than *two per cent.* of its weight of silver.

I procured neutral sulphite of ammonium by mixing ammonia with sulphurous acid. To ascertain the quantity of sulphite required for the complete precipitation of the silver from the ammoniacal solution of nitrate of silver and copper, I heated to the boiling point a definite volume of solution of sulphite of ammonium, and I found the volume of the solution of silver and copper which was decolorised by this salt. Experiment has, in fact, proved to me that so soon as the sulphite of ammonium, *sufficiently heated*, is not coloured blue by the cupric oxide dissolved in the ammonia, there remains no trace of silver dissolved in the liquid, because in this case all the copper exists in the cuprous state, the presence of which is incompatible with that of any compound of silver dissolved in ammonia.

The quantity of sulphite of ammonium necessary for the precipitation of the liquid having been determined, I added it to the argentiferous solution, and after being well mixed, it was left to itself for forty-eight hours in a closed glass flask, to prevent the contact of the air. At the end of this time about a third of the silver was reduced at the ordinary temperature, and was precipitated in the form of a shower of crystallised silver, of a greyish-white colour, and very brilliant.

I then put the decanted blue liquid, in quantities of ten litres at a time, in a water-bath at a temperature of from 60° to 70°. The time required to cause the elevation of temperature was quite sufficient for the complete reduction of the silver in solution, and for the reduction of the cupric sulphite to the state of cuprous sulphite; ‡ especially as I was careful to take a sufficient excess of solution of sulphite of ammonium.

The silver being eliminated, I decanted the liquid when cold, and proceeded to wash separately the silver precipitated from the cold and the warm solutions. This washing was performed by decantation with ammoniacal water; it was continued as long as the washing waters were perceptibly coloured blue by exposure to air, or precipitated chloride of barium. I afterwards left the silver for several days in concentrated ammonia, and then washed it in pure water.

If the solution from which the silver is precipitated has been diluted until it contains no more than 2 per cent. of silver, the ammonia left in contact with this metal is not coloured even after several days' digestion. There is no longer any copper for the ammonia to dissolve; it *dissolves silver* instead, for this metal is feebly attacked by the alkali under the influence of air, as is easily proved by evaporating liquid ammonia which has remained several days in contact with turnings of pure silver. This liquid always leaves a black shining mirror of nitride of silver by its spontaneous evaporation.

I prepared silver by this method at four different times, and in the last I operated upon 2500 grammes of silver at once. I have proved that by fulfilling all the conditions I have described, and *especially by carrying the dilution of the ammoniacal solution of the nitrates of silver and copper* to 2 per cent. of silver, we obtain silver of a rare purity. When it was wanted to form the precipitated silver into bars, I fused it with 5 per cent. of its weight of calcined borax containing 10 per cent. of nitrate of sodium, as I mentioned in the case of the silver reduced from the chloride by potassa and sugar of milk. I have also fused large quantities with the oxhydrogen blowpipe in a crucible of pure porcelain, or in a oxyhydrogen gas furnace in crucibles of marble lime.

* Abstract from *Memoirs of the Royal Belgian Academy.*

† I have found by several trials that French silver contains iron, nickel, and traces of cobalt, platinum, and gold.

On the Presence of Thorina in Euxenite, by* M. J. Chydenius.

In a note published in 1861 I mentioned that two specimens of sulphate of thorina, from Mosander's collection, were labelled as having been prepared from *euxenite*. This led me to examine this mineral for thorina. For this purpose I took some specimens from Arendal, in Norway, and after porphyrisation treated them with an excess of hot and concentrated sulphuric acid. The pasty saline mass so obtained was almost entirely soluble in cold water, and the solution on boiling deposited a precipitate formed of acids of the titanic group. The ebullition must be continued for some days to make this precipitation complete. After cooling, the filtered liquid is precipitated with ammonia, and the precipitate redissolved in HCl; to the liquid is added a warm solution of sulphate of potash; the precipitate thus formed contains thorina, ceria (if there is any), together with a certain quantity of titanic and other acids which have remained unprecipitated after ebullition of the dilute sulphuric solution. To separate these acids the precipitate is digested with oxalic acid; the acids of the titanic group dissolve, and a pulverulent residue remains of

‡ The liquid in which the reaction takes place becomes quite colourless if the copper contains neither nickel nor cobalt. If it contains nickel, it takes a slight green tint; it takes, on the other hand, a reddish tinge if there is cobalt in the dissolved metal.

* *Bulletin de la Société Chimique de Paris.*

oxalate of thorina, containing, perhaps, oxalate of cerium. To ascertain its nature I ignited the oxalic precipitate, dissolved it in warm concentrated sulphuric acid, and, after dilution, precipitated with ammonia. This precipitate was dissolved in hydrochloric acid, and the solution treated with hyposulphite of soda, which precipitates thorina, but not ceria. In this case I had a precipitate, which showed that I had been working with oxalate of thorina. The identity of the oxide contained in this precipitate with thorina was also proved by its density = 9·17 to 9·22, and by the analysis of the sulphate. The filtrate contained no other oxides, and consequently the thorina was not mixed with oxide of cerium.

Euxenite from Arendal contains, therefore, thorina, but traces only of oxide of cerium; and the analysis of the mineral (density 4·96) gave the following results:—

Mineral acids (titanic, niobic) . .	54·28
Gadolinite earths (yttria, erbia, terbia)	34·58
Thorina	6·28
Loss on calcination	2·60
	97·74

Euxenite also contains traces of ferrous and uranous oxides.

FOREIGN SCIENCE.

(From our own Correspondent.)

Paris, January 29, 1867.

We are every day becoming more and more accustomed to the use of the electric light. In a few days, thanks to the initiative of H.I.H. the Prince Napoleon, and the commander of his pleasure yacht, M. Georgette Dubuisson, it will be adapted to a ship for the first time, and also for use at sea; at a later period it will be probably established on board vessels of the first class, and those of ocean transport. On Tuesday evening, in the Bois de Boulogne, at the grand skating *fête*, fifteen electric lights erected for the purpose lit up, *a giorno*, the whole scene of lake, island, ice, skaters, and spectators. The effect was splendid. This lighting up was executed by M. Serrin, and was remarkable for its steady brilliancy, while, at the same time, it was simple, economical, clean, and very powerful. For each of the fifteen batteries there were collected forty Bunsen elements placed in a subterranean chamber which concealed the battery from sight as well as prevented the odour of nitrous gases from annoying the spectators. By the side of this pit there was fixed a pillar, hollow within, through which the wires passed to the platform, solidly and at the same time slightly constructed. On this platform was fixed the electric light established by M. Serrin. It was arranged catoptrically, as in the lighthouses of Havre and Odessa, furnished by the Alliance Company of Paris, and was placed on rails; thus, as soon as the carbon ends were burnt away and the light diminished, the man in charge had nothing to do to renew the splendid light but to push, by the hand, a newly lighted lamp, which instantly supplied the place of the faded one. When this was burned out, another lamp was rolled into its place, capable of burning again several hours. By this arrangement a single additional lamp was sufficient (or a sixteenth one) to conduct the service rigorously carried on, and the interruptions of which were quite imperceptible.

It is high time that we seek to make the electric light perfectly stable and effective to be used in public works in urgent cases. We have already spoken of the immense services rendered by this light in the workshops of the Northern Spanish Railway. Several questions have been addressed to us inquiring about the new machine of Mr. Wilde, of Manchester, which is capable of rendering the electric light more facile and abundant. We have always answered, "*Let us wait for the result.*" The Alliance Company is to receive at the end of April, or in the course of September, its first Wilde's instrument.

One of the persons in the employment of the Alliance Company went to Manchester to receive the machine, but he would not accept it until it had shown a light sensibly constant during six or eight hours in a lighthouse. Mr. Wilde thought that the moment for submitting his engine to this severe test had not yet arrived, and that in this actual model, with a velocity of 1500 to 2000 revolutions per minute, the armature acquired considerable heat, and the light diminished in intensity; consequently, he asked M. Berlioz to wait till the end of March or the opening of the Exhibition of 1867. The same reason has made him defer sending the machine intended for the British Commissioners of northern lighthouses, which is on a smaller scale. In this way practical success is far behind considerable theoretical progress. At present the advantage rests with M. Berlioz, who gives his machines a number of revolutions rarely exceeding 300 per minute, and obtains an absolutely constant light. He is at present occupied at important improvements to the engine, which can double its power and secure its future success.

PROCEEDINGS OF SOCIETIES.

SOCIETY OF ARTS.

On the Synthesis of Organic Substances, by Dr. F. Crace Calvert, *F.R.S., F.C.S., &c.*

(Continued from page 19.)

Allow me to call your attention to another series of facts, by which M. Berthelot has also demonstrated the possibility of producing organic substances from mineral elements. The starting point of this series is a gas well known by name to all my hearers. It is called "fire-damp," owing to the fact that it exists more or less in all coal-pits, and that when it is liberated in large quantities, and gets mixed with the atmosphere, it produces a most explosive mixture, the result of which is the destruction of thousands of lives in this country. This gas also bears the name of marsh-gas, from the circumstance that it is a constant product of the slow decay of organic matter. In fact, some twenty or thirty years ago, when a lecturer wished to illustrate the properties of this gas, called also light carburetted hydrogen, as compared with olefiant gas, which is called heavy carburetted hydrogen, his assistant had to proceed, as I have done myself, into marshy districts, and, stirring up the mud, collect the few bubbles of gas that escaped from the swamp. This operation—to collect a gas mixed with impurities—which was far from agreeable when it had to be done in January or December, has been obviated through the progress of chemistry. Some twenty years since Dumas found that when he heated in a retort a mixture of dry acetate of soda with baryta, a gas was generated which was marsh-gas, resulting from the following reaction:—The acetic acid of the acetate of soda unfolded itself into carbonic acid, fixed by the baryta, the remaining element being marsh-gas. But Berthelot has gone a step forward, and he has succeeded in producing fire-damp or marsh-gas direct from mineral elements. He has effected this interesting discovery by passing over some heated copper foils, placed in an earthenware tube, a mixture of two substances—namely, sulphuretted hydrogen and sulphuret of carbon. Under the influence of heat, the sulphur of the sulphuretted hydrogen and the sulphuret of carbon unite with the copper, whilst the hydrogen of the sulphuretted hydrogen and the carbon of the sulphuret of carbon combine together to produce marsh-gas.

This triumph of modern chemistry is most important, for if to marsh-gas you succeed in adding two proportions of water, it will be converted into methylated spirit, or wood naphtha, a substance now extensively mixed with alcohol to manufacture the product called "methylated spirit," so extensively employed in England at the present time in arts and manufactures, and which has been the means of removing the duty usually imposed by Government upon all alcoholic liquors capable of being used as a beverage, and enables English manufacturers to produce a variety of varnishes, &c., and to enter fairly into the field of competition with those countries in which alcohol may be considered a cheap article.

We may proceed a step further, and convert this alcohol of wood, as it is often called, into an acid by a similar process as we succeeded just now in converting the alcohol of wine into acetic acid. Thus, if in a flat vessel is placed a small quantity of wood naphtha, and above it is suspended a watch-glass containing platinum black, or purified charcoal, gradually the vapours arising from the wood naphtha come in contact with the platinum black, and are converted into an acid called formic acid—an acid which can be extracted from the insect called ant, or *Formica*. Therefore, from carbon and hydrogen M. Berthelot has produced not only wood naphtha, but formic acid, the product found in an animal. Formic acid has become, like many other organic substances, a curiosity one day, a commercial product the next. It is now manufactured artificially in large quantities, owing to its successful application in the production of those beautiful tar colours, especially blue, to which we have already referred in this lecture. But the application of formic acid, I think, will not be limited; it will extend widely with time, not only because it reduces with great facility metallic salts, especially those of silver —and thus will, no doubt, become in time the means of silvering glass, instead of having to employ the present costly method.

Whilst dwelling on formic acid, let me call attention to a direct artificial mode of production of that substance, also from mineral elements, by a most skilful process devised by M. Berthelot. All persons must have noticed, on a winter's evening, on sitting before the hearth of a good fire, which has yielded its gaseous matters under the form of flame, and has left a red glowing mass, a fugitive blue flame, which has received the name of oxide of carbon —gas which is, in fact, always produced when oxygen is brought in contact with an excess of carbonaceous mass in a state of incandescence. This blue-burning gas, or oxide of carbon, which is highly poisonous, is the gas chosen by M. Berthelot to produce formic acid. To arrive at this end he pours at the bottom of a large glass vessel a strong solution of caustic lye of soda or potash, filling the vessel with oxide of carbon. After giving a rotatory motion to the glass vessel, the oxide of carbon is absorbed by the potash, and each two chemical proportions of oxide of carbon, in fixing one chemical proportion of water, are converted into formic acid, which unites with the potash to produce formiate of potash or soda. Besides these two interesting discoveries of the production of organic substances direct from mineral elements, M. Berthelot and several other chemists have produced organic acids from other hydrocarbons derived either from destructive distillations of coals or other organic substances. Thus the acid existing in valerian root has been generated from a hydrocarbon existing in petroleum, called amylene. Propyle has been converted into propionic acid, naphthaline into benzoic acid, &c. Further, hydrocarbons which are found existing in the products of the distillation of coals, as well as those existing in petroleum, can be produced artificially by chemical manipulation, and these hydrocarbons are in their turn the centre of a great number of chemical substances, which chemists have succeeded in producing, either adding elements to them, or substituting certain quantities of their hydrogen by other elements, thus giving rise to a new series of products, and thereby a great variety of organic substances.

It will, therefore, be easy to understand how important it is for chemists to be able to produce artificially from one carburetted hydrogen another carburetted hydrogen, and this M. Berthelot has been most successful in accomplishing. By heating, at a high temperature, light carburetted hydrogen, he has succeeded in producing artificially benzine, a substance now so extensively employed, as I have told you in some of my former lectures, in producing most of the tar colours now used in trade. He has also obtained naphthaline by the same means; and you will perceive by the following tables that it is simply necessary to add to a carburetted hydrogen, say equivalent proportions of carbon and hydrogen, to convert it by successive addition into a series of hydrocarbons, susceptible in their turn, by means of oxidisation and other chemical action, of being converted into acids and other products:—

Ethylene . . .	$C_1 H_4$
Propylene . . .	$C_6 H_6$
Butylene . . .	$C_8 H_8$
Amylene . . .	$C_{10} H_{10}$
Caproylene . . .	$C_{12} H_{12}$
Œnonthylene . . .	$C_{14} H_{14}$
Caprylene. . . .	$C_{16} H_{16}$
Ethylene	$C_{32} H_{32}$
Cerylene	$C_{32} H_{32}$
Melissene	$C_{60} H_{60}$

Or,

Marsh-gas or formyl . .	$C_2 H_4$
Hydride of acetyl . .	$C_4 H_6$
,, propyl . .	$C_6 H_8$
,, butyl . .	$C_8 H_{10}$
,, ralyl . .	$C_{10} H_{12}$

The eminent Dr. A. W. Hofmann has succeeded in producing, of late years, a great variety of organic substances, by substituting for the hydrogen which enters into the composition of ammonia or hartshorn (composed of three atoms of hydrogen and one atom of nitrogen) some of the above carburetted hydrogen, thus giving rise to a most interesting series of products, many of which in time will become extensively employed in arts and manufactures. I cannot leave this part of my subject without mentioning the names of Drs. Frankland and Williamson, Messrs. Duppa, Church, Wanklyn, Perkin, and Foster, among our English chemists, who have the most contributed to the progress of organic chemistry by their successful researches in reproducing artificially organic substances, on some of which I shall have the pleasure of dwelling fully during this course of lectures. There are other discoveries not less interesting, but which are in themselves too abstruse, and which involve too many scientific data, to justify me in bringing them before you in addresses intended for general readers, and not especially for a particular branch of professional students.

The lecture was concluded by illustrations with apparatus, and giving an outline of the methods followed by chemists to determine the elementary composition of an organic substance. Without entering here into all the details of manipulation necessary, and a description of the apparatus used for ascertaining these compositions, we may state that the purpose of these operations is to determine the exact quality of carbon charcoal, and the exact proportion of hydrogen gas which exists in 100 parts of an organic substance. This being determined, the figure necessary to reconstitute the 100 parts of the organic substance employed is represented by oxygen, and it is easy to calculate, by employing chemical equivalents, what is the formula which that organic substance should have. To determine the amount of carbon and hydrogen in the substance, it is placed in a tube, and after being carried to a red heat it is subjected to the action of

oxygen, either employed as a gas, or in contact with a substance, such as oxide of copper or chromate of lead, which yields oxygen with facility. The result is that the carbon is converted into carbonic acid, which is absorbed by alkali, and its amount accurately determined, and the hydrogen of the organic substances is converted into water, which is condensed by means of oil of vitriol, and also its proportions accurately ascertained. With these data it is easy to determine the number of atoms of hydrogen, carbon, or oxygen which exist in organic substances. As to organic substances which contain nitrogen, the proportions of this gas in 100 parts of the substance submitted to elementary analysis is determined either by collecting it as a gas, and from its volume calculating the amount in the substance, or it is converted into ammonia, which, in its turn, is absorbed by sulphuric acid, and its amount also accurately ascertained. By these methods the amount of nitrogen in the organic substance is known.

ACADEMY OF SCIENCES.

January 28, 1867.

(FROM OUR OWN CORRESPONDENT.)

NOTE accompanying the presentation of a map entitled, "*Ethiopia, No. 3: Simen et Zimbila,*" by M. Antoine d'Abbadie. The interest of this map is concentrated in the Simen, a mass of trappic formation interspersed with numerous precipices, some of which are of vast depth, and expose basaltic columns in several points of their bases. The culminating point of this chain is the mountain Ras-Dagan, which attains a height of 15,138 feet, about 659 feet lower than Mont Blanc. This is the most elevated point in the African mountains ascended by a European traveller; the low latitude explains this, being only 13° 14′ N. The snow rests on the summit for a very short period of the year, and none remained on the surface during the visit to the highest point by M. d'Abbadie on May 15, 1848. The slopes of the massive chain are so abrupt that the valley, of the length of nearly five miles, between Sawada and Jucatkab presents a unbroken line of precipices 2624 feet high. At the north-east, on the slopes of the Buahit, several of the companions of M. Abbadie died of cold on October 3; whilst at the ford of Takkazi, at 120 kilometres further off, at an altitude of 3071 feet, a thermometer laid on the ground marked a temperature of 70° C. This map is the eighth that he has published of Ethiopia. Two other maps and an index-map will complete the *ensemble* of the positions that the author has determined by expeditious geodesic measurement, as well as by details and sketches collected on the spot.

M. Abbadie purposes publishing at a future period a general map of Ethiopia, on which he will add to his series of positions all the results of the labours performed by the European explorers, and all the information that can be obtained from native travellers who have supplied him with data upon the neighbouring countries remaining unknown up to the present time to our geographers.

M. Emile Blanchard, in presenting a memoir "*On the Heart of Insects and Mollusca,*" by M. Alexandre Brandt, published in the *Bulletin of the Academy of Sciences of St. Petersburg*, remarked that the author had particularly in view in this paper to demonstrate that the motions of the heart in insects and certain mollusca are not determined in any way by the extrinsic muscles. The pulsations continue with the same intensity during a certain time after that organ has been completely isolated.

M. Peligot communicated, in the name of M. Kessler, the following:—Some years ago M. Kessler introduced into the manufacture of crystal glass the process of engraving by hydrofluoric acid, employed upon a resinous coating, deposited mechanically by means of a stencilled impression on paper. This is the process employed at Baccarat, Saint-Louis, in the factory of M. Maréchal at Metz, &c. At its origin the engraving was done transparently; since that period it has been successfully used in giving a dull surface.

MM. Tessié du Mottay and Maréchal, jun., have composed alkaline fluoride baths with the addition of acids now employed in the manufacture of crystal glass. They attribute the formation of the dull surface to the insolubility of the fluorides of lead and calcium. M. Kessler states and proves that, on the contrary, the salts employed give rise to fluosilicates of imperfect solubility, which become solidly attached to the glass in the form of minute granular crystals, and act as a finely disseminated coating. The result is that the surface of the glass presents inequalities, having the appearance of fine sand. If the adherent deposit is not crystalline, or if the crystals are too small, there is no dull surface.

Finally, M. Kessler has succeeded in composing, with fluorhydrate of ammonia and hydrochloric acid, properly thickened, an ink with which, with any pen, ineffaceable characters can be traced on the glass, thus rendering great service in laboratories for labelling bottles and correcting the divisions of areometres, densimetres, &c.

M. Chasles presented to the Academy a copy of the work by M. de la Gournerie, entitled "Researches on Symmetrical Tetrahedral Regular Surfaces." It consists of three memoirs, on which a report had been already made by Messrs. Chasles and Bertrand. The author had also taken measures for the printing of the work, to which he had to add some further developments. For this reason, as the commission stated, the insertion in the *Receuil des Savants Etrangers* was not demanded. The work certainly contains many new developments, and four notes by Mr. Cayley. M. de la Gournerie explains in the following passage how he had obtained the co-operation of our celebrated correspondent:—"Some weeks after the publication, in the *Comptes Rendus*, of extracts of my two first memoirs, Mr. Cayley was kind enough to congratulate me thereupon, and to communicate to me some very elegant equations on the surfaces that I had made known. This step taken by the celebrated geometrician impressed me with a deep feeling of gratitude, and it led to a correspondence between Mr. Cayley and myself, which was of great interest to me. Mr. Cayley sent me for this work a note, in which are reproduced some details of his first communication. He, moreover, authorised me to dispose of his letters as I wished, and I have extracted three fragments, which I present under the form of notes."

M. Gustave Lambert, hydrographer attached to the French marine service, made a communication "*On the Laws of Isolation.*" It referred to the temperature of the zones of the boreal regions, or to the power exerted by the diurnal isolation of the sun, the principal cause of this temperature. The power of isolation in a certain place ought not to be confounded with the thermometric effect which is its consequence, but which depends upon a number of variable causes analysed by the author, and of which the technical details have been sent in an extended memoir upon isothermic lines, &c., &c. Designating by L the heliocentric longitude of the sun, w = the obliquity of the ecliptic, w' = the angle formed by the axis of the earth with the circle of isolation, an angle which is equal to the declination, l = the latitude, we have the following equations to represent the graphic *trace* of the curve of isolation at each parallel and at each season:—

$$\text{Sin } w' = \sin w \sin L$$
$$x = L \cos (l - w')$$
$$y = L \cos (l - w') \tan w' \; Sw \; (l - w')$$

in which x represents the power of the diurnal isolation.

M. Edmond Becquerel, on the part of Messrs. Pouillet and Babinet, made a report, completely favourable, upon a memoir presented by M. F. P. Leroux, on August 20 last entitled "*Theoretical and Experimental Researches on*

Thermo-Electric Currents." In a long and important work the author had stated and verified a great number of new laws, and given the explanation of a great number of mysterious phenomena. He was led to the conclusion that each body possesses *à priori* an electric tension measured by a function of the identical temperature for all bodies for each of them; that thermo-electricity is a property of matter, and not an accidental occurrence in bodies; that the conception of absolute electric tension, as a function of the temperature, is destined to account for atmospheric electricity, and to solve the difficult question of the pre-existence of chemical or electric action, thus affording a great progress in the identification of heat and electricity. The commission notes, wich all reserve, the theoretic views undemonstrated by practical experiment. But it asks the Academy to thank the author in the warmest terms, and to recommend him to prosecute his studies, inserting the first memoir in the *Recueil des Savants Etrangers*, one of the greatest honours he could receive.

M. Delaunay presented the first copy of the 29th volume of the *Mémoires* of the Academy, devoted entirely to his theory of the moon. This is the second part, of which the first appeared in 1860. Immense formulæ, interspersed with some lines of text here and there; that is what is in store for the very few—nay, rare—readers of this gigantic work, irreproachable in an algebraic point of view. M. Delaunay cordially thanked the Academy, and he had good reason to do so, since these volumes have cost them the fabulous sum of 1000*l.* to 1200*l.* As a *chef d'œuvre* of typography, it reflects great credit on the printing establishment of M. Gauthier-Villars and M. Bailleul, under whose direction the work was impressed. M. Delaunay had at first carried his calculations as far as terms of the seventh order; later he found that they must be pushed up to the eighth and even to the ninth degree. It appears, however, that this is not enough, since a geometrician very timid, but of an excessive delicacy, M. Puiseux, has followed in the same track as M. Delaunay, and gone much further, in not supposing any more fixed ecliptics, and in taking into account the changes which the elements of the sun are liable to. We frankly avow that the presentation by M. Delaunay himself of the memoir of M. Puiseux seems to us in point of view of the theory of the moon to be a veritable suicide; inasmuch as he casts a doubt upon, or calls into question, all the conclusions of his vast store of formulæ.

M. Leverrier stated that the learned Director of the Marseilles Observatory, M. Stephan, had discovered, on Tuesday, January 22, a telescopic comet, of which he could not determine the position till Friday evening. Right ascension, 2h. 34m.; North Polar distance, 74° 26′.

M. Delesse presented a memoir on his researches upon the littoral deposits on the shores of France made during the last few years. He finds that they present a very varied mineralogical composition at the level of high water, because they contain the *débris* from adjoining shores, but that at the level of low water the structure is much more uniform. At the bottom of the ocean it remains constant over a great extent. Thus, whatever be the nature of the rocks contributing to the formation of the deposit, the sea is not slow in destroying them; and we find everywhere the minerals, which have escaped from its action, either by their hardness or their unalterability. Of all minerals deposited by the sea at low water mark, the most widely spread is hyaline quartz. This is explained by its hardness and abundance.

NOTICES OF BOOKS.

Buckmaster's Physiology. London: Longman and Co., Simpkin, Marshall, and Co. Dublin: Ward and Sullivan, 27, Marlborough-street. 1866.

We notice this useful school book, not because it is about physiology or appropriate for review in the Chemical News, but simply as being worthy of insertion amongst the curiosities of literature. "Buckmaster's Physiology" is written by Mr. John Angell, and published by two eminent London firms, and also by one at Dublin. There is no clue given to us of who or what Buckmaster is, or what connexion he or it has with the book. We do not know anything of a series of works bearing the name of Buckmaster either. The whole is a complete puzzle, and we should welcome an explanation of it from the author or publisher.

On the Results of Spectrum Analysis applied to the Heavenly Bodies. By William Huggins, F.R.S., F.R.A.S. London: W. Ladd.

This is a reprint of a discourse delivered by Mr. Huggins, before the British Association, at Nottingham, in August last, and is now published in a separate form, illustrated by eighteen photographs of the most interesting spectra, and of the apparatus with which they were observed. The author's reputation is sufficient to vouch for the correctness of his observations, and the conclusions he draws from them will show to what extent our knowledge has as yet been increased by this, the latest addition to the science of astronomy.

CHOLERA AND ANTISEPTICS, 1866.

(A) *The Arrest and Prevention of Cholera; being a Guide to the Antiseptic Treatment.* By A. E. Sansom, M.B. Lond. London: Churchill.

(B) *Asiatic Cholera.* By F. A. Burrall, M.D. New York: Wm. Wood and Co. London: Stevens Bros., Covent Garden.

(C) *Reprint from the Appendix to the Third Report of the Cattle Plague Commission.* By Wm. Crookes, F.R.S. London: J. H. Dutton, 1, Wine Office Court, Fleet Street.

(D) *Tenth Annual Report of the Medical Officer of Health for the Holborn District Board of Works, London.*

(E) *Handbills relating to Precautions to be taken against the Cholera.* Various.

(*Concluded from page* 8.)

As regards cholera, at present we can only mention its predisposing causes as those of zymotic diseases in general, but cannot yet place it in a more perfect class—*i.e.*, where there exists a predisposition to it specially, and not to any other zymotic disease.* Dr. Gibbons, writing after the ravages of cholera, calls attention to the necessity of this discrimination, in order that proper remedies may be applied, and means of prevention to be used against the recognised *causes* of disease should possess special interest to chemists, who have already done such good service.

"The Legislature and Boards of Health, in dealing with the unhealthiness of towns, have restricted their attention too exclusively to the prevention of epidemic disease. Not but that some of the measures prescribed and adopted, as the ventilation of dwellings and public buildings, do tend to mitigate the ravages of consumption and other tubercular diseases. But I think the prevention of the tubercular class will require a different description of measures from those which have proved to be serviceable against diseases of the epidemic class" (Dr. Gibbon).

Dr. Sansom throughout his book shows plainly with what advantage a knowledge of chemistry may be applied as a means of prevention of disease.

So much for cholera generally as connected with other diseases by certain causes. As regards the actual cause

* The importance of these theoretical considerations cannot be overestimated as regards rational and systematic disinfection. Thus, given any zymotic disease, if it be endemic remove the cause, if epidemic disinfect.

of the disease, Dr. Sansom professes himself an advocate of the theory of its causation by distinct organised germs transmissible from place to place, and arguments for this are very abundant. We will quote only a few.

Dr. F. A. Burrall writes:—"If a ship laden with poisonous serpents should stop on its passage at different ports where no such reptiles existed, and soon after its arrival these venomous creatures should be observed in those ports, the natural inference would be that they had been brought thither by that ship, and it would not be a sufficient reason for disbelieving it that in some other ports touched by the same vessel no such reptiles had subsequently made their appearance."

Pettenkofer says: "Without the least danger of making an error, we can assert that the substance in question (the ultimate cause of cholera), although quite unknown to us as a separate entity, must be of organic nature, and either a cell or a ferment."

So far the cholera has been shown to resemble in its cause the cattle plague and the epidemic diseases; the opponents of the theory of this causation must consider by their view cholera and cattle plague to be endemic in Britain, which is very doubtful. Speaking only of virulent Asiatic cholera, we think that it is sharply separated from diseases endemic amongst us; and even were we to admit that bad drainage, &c., might *per se* cause typhoid fever, we could not admit the same cause for cholera on general evidence. How does this poison spread?

"The labours of Pettenkofer, Snow, Delbrück, Budd, Griesinger, and others, have shown that the dejections from cholera patients, or those suffering from cholera diarrhœa, are a very frequent, and, as they claim, the chief cause of the propagation of the disease."

"The specific germ transmissible by human intercourse is the ultimate cause of cholera; it is transferred principally in the dejections of those suffering from choleraic diarrhœa, perhaps, also, by persons in good health coming from infected districts."

"In one instance, at Constantinople, the clothes, mattresses, &c., of the sick were washed at the fountain, and the water-pipe being unfortunately broken, the foul water communicated with the clean. In a single day sixty people died at Tatavola, which is a small portion of the city supplied by the infected stream."

From facts and opinions such as those Dr. Snow makes the following statement; we again quote from Dr. Burrall's work:—

"The poison itself is exclusively contained in the intestinal excreta of the infected person, that is in the vomit or dejections; there is nothing from the lungs or skin that produces the disease. This poison is not a gas or vapour, but a substance capable of existence in the fluid or dry form of matter; hence it can only be wafted a little way by the air, and when in the dried state can only be carried long distances by being attached to articles of clothing, or disseminated by the agency of water."

This is very generally believed at present to be a just expression of the facts known, as we know nothing of any other probable means. The same author, Dr. Burrall, further on asks if the poison may not be a gas or vapour, in the following words:—

"Is it safe to assert that the poison is exclusively contained in the intestinal excreta, or that it is not gaseous or a vapour, when it is so subtle as to have eluded the most searching examinations? Some points in this theory seem to be substantiated, as that the poison is (mainly) contained in the excreta, and that it may be carried on clothing or food; hence it is better to admit what is known, and patiently follow the teaching of facts in a further elucidation of those features of the disease which are as yet unknown."

But how do these reasons apply to the truth of the proposition? We compare with them the following extracts from the Cattle Plague report:—

"There are weighty reasons for deciding that the infecting matter is neither a gas nor even a volatile liquid. The almost infinite attenuation which a gas undergoes, owing to its rapid diffusion into the atmosphere, would render its supposed noxous influence imperceptible a few yards from the focus of infection. Moreover, the infection is capable of being carried considerable distances in clothing or running water, and in a variety of ways incompatible with the behaviour of gases. For these reasons, and many others unnecessary to adduce here, it seems clear that the disease must be communicated by the agency of solid, non-volatile particles."

Again, "There is no difficulty in admitting that the infection may travel for a certain limited distance through the air, and it is even likely that it may be carried longer distances by fogs, or heavy vapours, or by the gases of putrid decomposition; but it appears in the highest degree improbable that the germs should be able to retain their vitality for any length of time in the atmosphere."

If the view of its being carried by clothes and the person be admitted, then the disease is contagious in the limited sense of the word, as well as infectious, and this view seems to be held pretty generally now by physicians, and has the high sanction of Velpeau. "M. Velpeau considers the contagious character of the disease proved to a certainty, and the same is true of other prominent European physicians." (Burrall.)

Another cause for the rapid spread of the disease is pointed out by M. Worms, but fortunately many facts are not to be adduced in proof of his statement, from the early burial of the dead. M. J. Worms states that "the corpses of cholera patients emit the toxic agent in a greater degree than the bodies of the sick." (Burrall.)

With such statements and authorities, we may well rationally place our main reliance on antiseptics for the arrest of the spread of cholera, with a speedy interment of the dead, and, as Dr. Lankester recommends, more especially isolation of the sick, if merely for the prevention of concentration of poison where it cannot be properly rendered harmless by disinfection.

Having drawn these conclusions as regards preventive measures, it only remains for us to notice a subject before hinted at when dealing with the lessons taught by the cattle plague. Antiseptics have been recommended in the report as being of *both preventive and curative* value. The series of experiments bearing on the former were complete, that bearing on the latter were interrupted. As regards antiseptic prevention, we have accompanied all the authorities quoted, but for the conclusion of the subject we must follow Dr. Sansom, who has adopted a curative treatment which depends on internal disinfection, the only author that we know of who has carried out this plan of treatment. At University College Hospital during the last autumn, many cholera patients were treated by external applications only, while the spread of the disease was prevented by the free use of carbolic acid. It was a striking fact that the mortality under such treatment was certainly not more than in the class of cases there and elsewhere treated by internal remedies. Thus, the spread of the disease was prevented, and the more urgent symptoms were relieved. Dr. Sansom goes a step further, as we have before stated. As he argues, antiseptics are preferable to oxidising agents externally, so why not the same internally? In other words, sulphites and carbolates as opposed to chlorides (calomel also causing a flow of antiseptic bile by specific action), tannates, &c., &c. Thus, at page 116 he writes:—

"We have two agents which fulfil the indications which we require to render inert an organised poison: 1, the sulphites; 2, carbolic acid. These have their mutual advantages and disadvantages. The first is administered with greater facility, but is the more rapidly metamorphosed into other less efficacious compounds, and no doubt has less powerful action upon the germs. The

second, on the other hand, has a 'stinging' effect on sensitive surfaces, and its taste is to some people disagreeable. Happily, having the two agents, we can in great measure neutralise the objections."

But the author in his treatment prefers the sulphite of soda, as being more manageable, perhaps from the quantity of soda salts in the serum of the blood, and so more immediate action — apart from that, sulphurous acid proper. At page 120 we find "The treatment of cholera by doses of carbolic acid has been tried, and though it is as yet, *sub judice*, the reports from the *Belleisle* hospital ship state that it would appear that 'the carbolic acid system had been most successful.' The advantage of carbolic acid is that it can not only be administered by stomach and bowel, whereby it acts upon the organic matter in the alimentary tract, but it is most undoubtedly absorbed into the blood, and, moreover, being a volatile body, its vapour can easily be introduced by the lungs."

One drop of carbolic acid is given by Dr. Sansom with three drops of chloroform in gum-water. We do not learn whether or not carbolates or sulpho-carbolates of soda have been tried without the addition of chloroform, but the more soluble the salt the better. A sodium salt would be assimilated more easily by the serum of the blood, which seems the more affected of the blood constituents. The potash salts may be more soluble, but those of soda should first be tried, if by their means sufficient acid be introduced into the blood.

The author, in addition, advances a theory of the action of the poison germ, which it would be out of place to notice here. We may say that it is scientifically argued, and is certainly worthy of a place with other theories worked out in a similar manner. The more we get of them the better will it be for medical science. We can recommend Dr. Sansom's work as being an excellent example of what original research may effect, even when the subject has been treated as fully as "cholera" has; and Dr. Burrall's book we may also offer as an example of a careful and guarded expression of all that has been said of Asiatic cholera during the present and former epidemics in the smallest possible space. We hope that all the books and pamphlets that we have cited (to use the words of Dr. Sansom) "will receive the friendly criticism of all who desire to discover the most truthful answer to a momentous question."

CONTEMPORARY SCIENTIFIC PRESS.

[Under this heading it is intended to give the titles of all the chemical papers which are published in the principal scientific periodicals of the Continent. Articles which are merely reprints or abstracts of papers already noticed will be omitted. Abstracts of the more important papers here announced will appear in future numbers of the Chemical News.]

CORRESPONDENCE.

Ansell's Fire-damp Indicator.

To the Editor of the Chemical News.

Sir,—It is funny that a correspondence conducted in another paper should be imported into your columns. "Don't Blow Up" seems to be really desirous of information. He is, therefore, different from the other correspondent, whose only object was to "pay me out" because I would not reply to some of his stupid letters. To that man I again say "simply untrue," because he wilfully misrepresented.

The untruth to which I took objection rested on the fact that the writer of a paragraph had for his own purposes jumbled up the facts connected with two instruments intended for different purposes. He says, "It is possible, and even easy, with an Ansell's indicator, constructed to give an indication at any given point (say 5 per cent. of fire-damp in two minutes, for example), to change the atmosphere in which it is placed from pure air to pure fire-damp without any indication being given. It would be simply necessary to place the indicator in a box of pure air, and introduce (say) 3 per cent. of fire-damp every five minutes." Supposing that I am required to meet this case, I should use a thin slab of marble one-eighth of an inch thick, and so give the warning in two minutes or less, and by the same instrument show the gradual increase with perfect certainty. The writer did not accept my invitation to come and see because he did not wish to be convinced, and had he been convinced would not have adjusted his misrepresentation. That writer says further on, "But unfortunately the very principle upon which the invention is based has compelled practical men to demand the complete demonstration of the contrary before admitting that its introduction into collieries would not lead to increased danger," &c. To this untruth I reply that no such demand has been made; while, on the contrary, I have practically demonstrated the truth of all my statements to the entire and expressed satisfaction of bodies of mining engineers in various districts, who were invited to meet me by Mr. J. W. Day, the secretary of the Mining Association of Great Britain, and who purposely selected such pits and places as would present, in Mr. Day's own words, "every difficulty likely to occur in coal-pits." The engineers who accompanied me never once asked other demonstration, They invariably said, "Well, Mr. Ansell, if fire-damp be present you show it by your instruments, but we know fire-damp is there; tell us how to get it out."

In replying to my comment on the paragraph above alluded to, the editor of the *Mining Journal* says—"In the table of experiments included in that paper, Mr. Ansell notes a case in which he thinks that the indicator did *not* indicate correctly, and gives the alarming statement, by way of excuse, that 'it was agreed that this was held ten seconds too long, as the index had travelled backwards.'" In reply to this, I would say that the untruth is in the intention of the writer, not in the words he uses. He has to bolster up a rotten case. The simple fact is, that when I was at Wigan Mr. Gilroy had taken down the pit with us a collier, whom he believed to be specially intelligent, and who really was beyond the average in that respect. On the day following the public trial I had occasion to go to Mr. Gilroy's drawing office to fetch some apparatus, because Mr. Gilroy had arranged a private trial for the benefit of his underviewers, and there I found the intelligent man of whom I have spoken actually with coal-gas practically demonstrating by experiments my invention to firemen, clerks, and colliers—in all about twelve. I listened with no little interest to his lecture; it was without fault; but he could not understand *effusion*, and called it incomprehensible. The result was that I showed him, and he afterwards went to the pit with the rest of us; and there, after our experiments had satisfied everybody, I practically showed the man that by holding the pocket indicator too long, the hand would travel backwards; and of course it did so. Seeing this, the man said, "Then it is really necessary to hold that particular instrument exactly as long as you tell us, just as it is to take eggs out when they are boiled?" It was thought well to insert these two experiments, else cavillers would say they were not all put down. But Mr. Baldwin said to the gentleman who wrote down facts—"Write 'It was agreed that this was held ten seconds too long,' and *that will make it fair to Mr. Ansell.*"

Here is another proof of the untruth of the writer—that, to bolster up his absurd statements, he lugs in another instrument than the one he was before criticising.

If the article which you so kindly inserted be read with this letter, I feel sure that the whole matter will be quite transparent. I am, &c. George F. Ansell.

Royal Mint, January 24.

P.S.—This letter is deliberately written, notwithstanding its apparent ill-nature.

Determination of Phosphates.

To the Editor of the Chemical News.

Sir,—The letter of Dr. F. W. Griffin, in reply to "A Smatterer," relative to the determination of phosphates in commercial analyses, while entering into some of the causes of the discrepancies between the results of different analysts, fails to explain why the precise disagreements pointed out should exist, though, indeed, the Doctor seems to take it for granted that they do exist.

"A Smatterer" says that "when samples of superphosphate, which contain the highest percentage, say 35 to 38 per cent. of soluble phosphate, and 2 or 3 of insoluble, are analysed by two different men, a 'high' and a 'low' analyst, we get similar reports; but with about 25 per cent. soluble the difference is constant, viz., 2 to 2½ per cent." Upon this Dr. Griffin remarks that "the discrepancies adverted to by the writer can scarcely be obviated, whilst a full analysis is expected for an inadequate fee." Now, "A Smatterer" evidently does not allude to discrepancies exhibited by full analyses, but only those between two different determinations of soluble phosphate. Moreover, he does not state, or give us to understand, that the partial analyses of which he complains were performed "for an inadequate fee." On the contrary, being a manufacturer of "several years' experience," he could not well be capable of offering to a professional man an amount which he must be well aware would not repay the latter for the necessary care and trouble bestowed on such analyses. Besides, if the cause of these discrepancies was "an inadequate fee," why should the "high" and "low" analysts send in similar reports in the case of superphosphates containing from 35 to 38 per cent. of soluble phosphate, and only differ when the sample contains about 25 per cent. soluble, and then, mark you, by a constant quantity, viz., 2 to 2½ per cent?

For my own part, if the discrepancies alluded to by "A Smatterer" really existed as a general rule—and I

am inclined to think that they are merely the results of his particular experience—they might be accounted for by supposing that when samples containing the highest percentage of soluble were submitted to analysis, both "high" and "low" analysts employed the most accurate process at their disposal, and therefore got the same results. On the other hand, when ordinary samples, containing about 25 per cent. of soluble, are analysed, we may suppose that the "high" and "low" analysts employ two different processes of a simpler and more expeditious, though less accurate, character, and therefore obtain results differing by a constant quantity.

This is, however, only one mode of accounting for "A Smatterer's" observations, supposing them to be of a general character, but I can only say that these observations do not agree with the results of my ten years' experience as an analyst of superphosphates.

I am, &c.

John Newlands, F.C.S., late Professor of Chemistry in the City of London College.

Laboratory, 19, Great St. Helens, E.C., Jan. 14.

On some Facts seemingly Overlooked in the late Explosions in Coal Mines.

To the Editor of the Chemical News.

Sir,—While reading over the evidence tendered at the inquest at Barnsley at various times, but more particularly on Monday, the 21st instant, I was very forcibly struck by the absence of all mention being made of the power which quick or slaked lime possesses of absorbing from the atmosphere, and thus rendering harmless, the carbonic acid (after- or choke-damp) which is produced in such abundance by these explosions, and which acts so deleteriously on human life. No mention either is made of the mixture proposed by Professor Graham of slaked lime and crystallised sodic sulphate (Glauber's salt), for use in atmospheres containing this gas, to be put in a cloth and placed over the mouth and nostrils, as a medium through which the air in such places may be breathed without any bad effect, the lime absorbing the carbonic acid.

These points, I consider worthy of notice, as they may serve, to some extent, to lighten the effects of these explosions; and, even though explosions do not occur in all mines, it is well known that carbonic acid is one of the invariable products of respiration, both of man and animals; and also that the gas escaping from the blowers does not always consist of marsh gas alone, but variable mixtures of fire- and choke-damp, and perhaps sometimes solely of the latter. It therefore follows as a natural result, that if quick or slaked lime be exposed in trays or in any other form to the draught of air through the mine, and also in the workings, both old and new, the air will be purified to a greater or less extent from this noxious ingredient, and rendered more wholesome to the miners.

Then, again, I think the decision of the engineers assembled to discuss and decide with respect to the mode to be adopted for putting out the burning coal in the Oak's pit may reasonably be called in question, as to its being the best that could be employed under the circumstances. It is evident from the statements in the papers as to the rubble which was thrown down the shaft, that, before the remainder of the bodies can be got at, or the mine ventilated, this heap of rubble will have to be removed; and not only so, but it is possible, as stated in the extract given below, that on air being allowed to pass through the mine, the coal may, from insufficient cooling, take fire again, and become as bad or worse than before. Whether this will be so remains to be seen.

A better method (I will not say the best) would have been that introduced by Mr. Goldsworthy Gurney, of filling the mine with carbonic acid, which was used with perfect success on several occasions. One instance which is given in Part II. of Professor W. A. Miller's "Elements of Chemistry," I extract in proof of its efficacy:—"The burning waste of Clackmannon, situate about seven miles from Stirling, had been for thirty years on fire. It occurred in a seam of nine-foot coal, and extended over an area of twenty-six acres. The fire was thus successfully extinguished:—About 8,000,000 cubic feet of gas were required to fill the mine, and a continuous stream of impure carbonic acid was kept up night and day for about three weeks. The difficulty lay not so much in putting out the fire, as in cooling down the ignited mass so that it should not again burst into flame on readmitting air. In order to effect the necessary reduction of the temperature, water was blown in along with the carbonic acid, in the form of a fine spray or mist. Subsequently, cold air, mixed with the spray, was blown in, and in a month from the commencement of operations the fire was found to be completely extinguished."

I do not give here the details of the process, as it would be too great an encroachment on your valuable space, but beg to refer all requiring further information to the work from which the above is extracted.

I am, &c. W. H. Wood.

Halifax, January 29.

Testing the Value of Glue.

To the Editor of the Chemical News.

Sir,—In answer to an inquiry, I lately drew your attention to Dr. Weidenbusch's paper on "The Determination of the Value of Glue," and I am induced to send you to-day as compressed an abstract as possible of his paper—the more so, as he found the quantity of gelatine present no criterion of the tenacity of the glue, which latter process is recommended by a correspondent in your number for January 11.

The author found as the result of many experiments no chemical determination to answer; he found it impossible so completely to precipitate a solution of glue by tannin as to deprive the evaporated filtrate of the characteristic smell of glue; and, even if this were possible, the amount of substance precipitated by tannin is no indicator of the comparative tenacity of the glue, in which consists of course its value. Whatever chemical means may be employed hereafter in testing glue, they will always require a verification by physical means, which the author accomplishes in the following manner:—

He casts the very finest plaster of Paris into sticks of mathematically exact dimensions in a mould of French chalk, which combines the smoothness of metal with the absorbent power of clay. Into a piece of French chalk about 1¾ inches high, a number of conical channels are drilled, about ¼ inch apart and ¼ inch in diameter at one end, and ⅛ inch at the other; these channels must be polished very smooth, and must be of exactly the same dimensions, the success depending upon the uniform size of the sticks. The mould is placed with the narrow aperture of the channels downward upon a piece of caoutchouc and a little wooden block. The gypsum is weighed out, 18 grains for each stick, well mixed with an equal weight of water, and poured into the mould. In order to prevent any air bubbles being retained, a fine wire is pushed up and down the channels, the casts are then left to stand for a couple of hours, the mould is warmed, and after 3 or 4 hours the solidified sticks are knocked out by a stout wire; they are smooth as if polished. A good stock is prepared, which is first dried by gentle heat, at last in a waterbath, till they do not lose any more in weight, when they are kept in stoppered bottles.

Now the principle of determining the value of glue is this:—If gypsum sticks are saturated with solutions of different glues, different weights or loads are required to break them with; and if the load required to break the gypsum alone is always the same, the difference is due to

the difference in the value of the glue. A little apparatus has been constructed to break the sticks, which, together with the mould, is sold by Mr. Desaga, of Heidelberg. It consists of a brass ring, with two deep notches, to receive the gypsum stick; the diameter of the ring is accurately divided into halves by a pin, placed at right angles; the ring is fixed to a stand by an arm and screw, and the apparatus is completed by a glass or iron beaker, suspended by three strings fastened to a hook, which is hung over the gypsum stick in the place indicated by the pin. This beaker has to receive the weight in mercury, and is closed at the bottom by the pinch cock for drawing off the mercury. During the experiment this beaker is also fastened to three other strings, to catch it as soon as the gypsum stick is broken by the load. These little sticks being conical, it is important to load them always at the same place, which is determined by a little measure, consisting of a glass tube, one half in length of the sticks, closed at one end and well ground at the other; the stick being placed inside the tube, a lead-pencil easily marks the exact place.

The breaking value of the sticks themselves, dried at 100° C., was first determined, the mean of many experiments being 219 grammes, the greatest part of which is made up by the weight of the beaker, the remainder of course being mercury.

After this the quantity of glue was determined as absorbed by the sticks. Result as follows:—

Weight of stick in grammes .	1·163	1·135	1·180
,, glue ,, .	0·620	0·600	0·600
,, mercury in c.c. .	101	97	96·4

The figures show a fluctuation in the breaking weight, but considering its being very high, these fluctuations are not very important; and as the fracture of the sticks gives sufficient explanation of any irregularity, it is as well to make several experiments with the same sample, and select the result with those sticks which show after the experiment the most homogeneous fracture.

After this plan a great many samples of glue have been tested in the following manner:—The glue, dried at 100° C., is weighed, left in water over night, and next morning dissolved in a water bath, and so much water added as to make up the proportion of 1 glue to 10 water. About 1 c.c. of neutral solution of indigo is added beforehand, which makes the coating of the gypsum distinct. Several sticks are then placed into the glue solution for one or two minutes, taken out, and put vertically upon a glass plate; after which they are completely dried in a water bath. They are then placed into the ring of the apparatus, the beaker is suspended, and mercury allowed to run in till the stick breaks.

In order to find the absolute weight of the load required to break the single glue stick, the volume of mercury in c.c. must be multiplied by the specified gravity of the metal (13·5), and to the result must be added 219, being the weight of beakers, plus mercury, required to break the gypsum stick by itself. It will be found that a weight of about two pounds is required to break the best sample of glue. The author has tried in vain to ascertain any relation between the tenacity and specific gravity of the glue either in the solid or liquid state. He is also fully aware that his method is open to objection in consequence of the difficulty in obtaining sticks of absolutely the same size, in uniformly saturating them with glue, &c.; but this process is by far more satisfactory than the precipitation of gelatine by tannin.

Camden-square.

Preservation of Specimens.

To the Editor of the Chemical News.

Sir,—The preservation of specimens, chemical or mineralogical, in a museum has engaged my attention some time, and the plan that I intend to adopt is as follows:—Small zinc cubes could readily be made, if a quantity were ordered, and of a uniform size, say one or two inches cube; five of the faces could be soldered together, and the sixth upper one would be a glass plate fitting in a groove, and be so fixed by soluble glass and kept from any atmospheric change. The label and substance itself could be seen through this. Access to the specimens for analysis is easily allowed by moistening the compound fixing the glass. The inner surfaces of some of the cubes could be lined with the same soluble glass, to protect the zinc from chemical change, if such were likely to occur. Deliquescent salts could be compared with more stable ones—as the cupric sulphate, nitrate and chloride—by simply exhausting the air to some extent before fixing the glass plate. The whole would fit accurately into a shallow drawer of any convenient size. I think the plan will be feasible, and the interest will well repay the trouble.

I am, &c. Preserver.

University College, London, January 21.

Standard Thermometers.

To the Editor of the Chemical News.

Sir,—From a communication sent by Mr. H. C. Kay to the *Times*, it is stated that thermometers issued from one of the first houses in London, having Mr. Glaisher's certificate, differ materially from those certified at Kew. He writes:—

"Two years ago, requiring a first-class *maximum* registering thermometer for scientific purposes, I applied to Messrs. Negretti and Zambra, the eminent makers, for a standard instrument with the Kew certificate. Not having one of these at the time, they sent me (with my full approbation) one with Mr. Glaisher's certificate, No. 7381. The certificate stated that the reading was 0·5 deg. too high throughout the range. A few months ago, suspecting a more considerable difference than half a degree between this and several neighbouring instruments certified at Kew, I made a careful comparison, with the following result:—

Kew Instrument. Degrees.	Glaisher's Instrument. Degrees.
57⅓	59
70¼	72
79	81½"

When two such authorities as these disagree, it is difficult to know upon whom to rely. But surely there can be no difficulty in sending out any number of thermometers of an accuracy within 0·2 degree without any increase on the price. The process of making and graduating thermometers is so simple, and the ease with which they can be compared with a standard instrument so great, that makers ought to be expected as a matter of course to supply all their instruments, whether "certified," "guaranteed," or otherwise, accurate, within a limit of at least a quarter of a degree. By laying such stress on the difference between instruments "certified at Kew," and uncertified ones, manufacturers lead the public to believe that the accurate graduation of a thermometer is a matter of some difficulty, whereas it is really one of the simplest and easiest things in the world, to those who possess the proper appliances, and not very difficult even for an amateur. I am sure some of our noted thermometer makers will corroborate me in the above remarks.

I am, &c. Zero.

MISCELLANEOUS.

Photographs on Season Tickets at the International Exhibition.—In the programme of arrangements for the issue of tickets to the forthcoming International Exhibition, it is intended to render photography available as a means of identification of the owners of season tickets, which will not be transferable.

The price of the tickets for gentlemen will be 100 fr., those of ladies 60 fr. The signature of the ticket-holder must be given whenever it is demanded, but this condition is qualified by the following clause:—"However, the ticket-owners shall be exempted from the verification by means of signature, by giving or sending two copies of their photographed likeness, one of which will be affixed to the ticket." Weekly tickets at 6 fr. will be issued, but, according to the programme, only to persons who may present themselves at the office with their photographs. The ticket will be affixed to those photographs. Exhibitors will receive season tickets subject to the same conditions.—*The Photographic News.*

Labels for Reagent Bottles.—Messrs. Jackson and Townson, Bishopsgate Street Within, have published a very convenient sheet of reagent tables, according to the new notation and nomenclature. It is not every one who will recognise familiar tests under the names "Hydrammonic carbonate, $(NH_4)HCO_3$," "Hydric chloride, HCl," "Hydric-hydro fluo-silicate, H_2SiF_6," &c., but their difficulties will soon vanish when these labels are constantly before them. Teachers and students cannot adopt a better means of familiarising themselves with modern nomenclature than by using these labels in their laboratories. They are printed in large bold type, and are well gummed at the back.

The Thermoterion, or economic heat retainer, is the name given to a piece of apparatus which will be found exceedingly useful in laboratories. It consists of a series of concentric metallic or other vessels, the inner one containing a readily removable glass beaker; outside this is a space for hot water, which is supplied through a covered opening, and it is the heat from this water which keeps anything warm which may be placed in the glass beaker. Outside the hot water space is an air-jacket which insulates the hot water and obstructs the radiation of its heat. Air, being a non-conductor of heat, enables a high temperature to be maintained within the apparatus for many hours. As an experiment, boiling water was poured into the beaker and hot water space, and the temperature of liquid in the beaker was taken every hour. At the end of the first hour it was 186° F.; second hour, 171°; third, 159°; fourth, 149°; fifth, 141°; sixth, 133°; seventh, 126°; eighth, 119°; ninth, 113°; tenth, 108°. Chemists engaged in research, or wishing to prepare good crystals of any compound by very slow cooling, will appreciate the advantage of an apparatus of this character, which enables the crystallising operation to be prolonged for so many hours. It will be equally convenient when digestions, solutions, or pressure-tube operations are required to be conducted, and where an actual boiling temperature is not needed.

A Chemical Theory of Cell Formation.—Dr. C. Montgomery has written a very remarkable paper, read before the Royal Society, December 20, 1866, on the above subject. The whole paper has a very particular interest, and his facts are well worth verifying by all who have an opportunity of doing so. From preliminary observations rationally treated, the above gentleman made the following experiments:—A viscid substance was required, and myeline, after a long search, was found to be the one. When to myeline in its *dry amorphous* state water was added, slender tubes were seen to shoot forth from all free margins, "being sometimes wonderfully like nerve *tubes* in appearance, flexible and plastic." From this crystallisation was inferred, and this extension was prevented by an intimate admixture with the white of an egg; clear globules resulted from imbibition by a viscid substance. By further extensions of this observation and similar ones, globules with lively molecular movement were found. A typical cell with nucleus, and even nucleolus, and "the white margin so often mistaken for a cell wall, was always present." This latter fact will be a decisive answer to Mohl's theories. Mother cells were formed. Lastly, globules were obtained with another enclosed smaller globule, and this was sometimes multiple, like the typical pus cell. If, instead of water, serum be added to the thinly-spread myeline, bi-concave discs will form, only generally much larger than blood-corpuscles. The changes in theory effected by these precise facts will, of course, be very great. The author observes that "'cells" being thus merely the physical result of chemical changes, they can no longer afford a last retreat to those specific forces called vital. Physiology must aim at being something more than the study of the functions of a variety of ultimate organic units."

ANSWERS TO CORRESPONDENTS.

G. Lunge.—Received with thanks.

Metallurgist.—Dr. Percy's "Metallurgy," first volume, contains all the information you can desire on the manufacture of spelter.

Constant Reader.—The statements are certainly open to criticism, and will probably receive it.

F. Samuels.—We must decline to give the address required.

L. N.—Fine white blotting-paper will answer most of the purposes of a laboratory better than Swedish filtering-paper. The latter is very slow in its action.

C. N. will find the address of the manufacturer of the "New Filtering Apparatus" in our advertisement pages.

Books Received.—Lessons in Elementary Chemistry, Inorganic and Organic, by H. E. Roscoe, B.A., F.R.S.

W. A., Mass.—Dr. Hofmann's Report on Class II., Sect. A., Exhibition 1862, is out of print.

Distiller.—Böttger's test for copper in brandy is very good. Agitate a little of the suspected brandy with a few drops of pure olive-oil. If copper be present, the oil will acquire a green colour.

M. P. T.—The new edition of the Pharmacopœia will be out in a week or two.

Uses of Naphthaline.—*T. A. R.* writes as follows:—"I find a very considerable quantity of naphthaline in distilling my tar, and am too distant from any likely market where it might be sold. Could any of your numerous correspondents suggest any use for it? Such information I would not object to pay for. If there are any uses, although but in a moderate way, the knowledge of them would be of value to those, like myself, in a remote corner."

E. K.—For an explanation of the term "triatomic," as applied to glycerine, see Wurtz's "Introduction to Chemical Philosophy," page 151. To answer your questions fully, it would be necessary to give an abstract of the book.

T. J. Y.—The best cement for attaching jewels to metal or to each other is made by dissolving a quarter of an ounce of gum mastic in two ounces of alcohol; then soak half an ounce of isinglass in four ounces of water for twenty-four hours, evaporate in a water bath till it is reduced to two ounces, add two ounces of alcohol, and strain through linen. Then mix, whilst still warm, with the solution of gum mastic. Add one drachm of powdered gum ammoniac, and triturate in a mortar till perfectly incorporated. This is sometimes called Armenian cement. It resists moisture and dries colourless. It will unite glass, china, and even polished steel. When required for use, it must be softened by placing the bottle in hot water.

Received.—R. J. T.; S. Muspratt, M.D.; A Subscriber.

LONDON WATER: PAST, PRESENT, FUTURE.

FUTURE.

We have tried to show that the questions of sewerage and water supply always require a discussion in common, from the present intimate relations of the two systems. The impurities from the one may influence the other, either locally or from a common centre, or by necessity from forces known to be at work. By the second means, many have tried to show, on the ground of infiltration of the soil by sewage, that great evils may be brought about, as implied by the Registrar-General in his last quarterly report:—"3691 deaths by cholera and 740 by diarrhœa—that is, 4431 together—occurred in the East London districts, among 607,945 people supplied with water chiefly from the Old Ford reservoir of one company." The comment of Dr. Frankland on this reservoir is:—"It, as I was informed, is excavated in clay, but the side next to the navigation branch of the foul River Lea is of gravel. Nevertheless, the position of this reservoir with its two and a half acres of floor, sixteen feet below the surface of a badly-drained district, is fraught with much peril during the prevalence of epidemic disease." Dr. Hawksley* forcibly shows the evils that have their origin from the third cause:—"We fling into this immense system of tubes every day in London 4224 tons of human organic matter, spread over acres and acres of surface, kept continually moist by the water poured through, and constantly aerated by a current of air rushing from the periphery of the system to the centre; wherever there is an opening, be it gully-hole, or drain-pipe, or water-closet, there must ever be issuing pestiferous gases." We may add, not gases only, but also that by vapours particles are carried mechanically, like dust by a gale of wind. The same author, in his treatise on "Matter," observes also:—"The larger the sewers, the greater the surface for refuse matter—the greater the volume of air with a current, in a tube from the lower to the higher level, from the colder to the warmer atmosphere." Dr. Sanderson's manometer demonstrates the constant upward pressure of the gases within the sewers; and it is obvious that for every inch of barometric pressure diminished, one-thirtieth of the whole volume of foul air in the sewers must ascend into the town. No wonder that we can foretell rain by the odours from the drains and gully-holes." Thus, then, with three classes of pollution existing, is it rational to bring water by 183 miles of aqueducts from the Severn at the cost of 8,600,000*l.*, or from Westmoreland, a distance of 240 miles, for 9,650,000*l.*, if it is to be supplied as at present? The schemes are truly magnificent; but, leaving out the question of the cost, would it be wise for 3,000,000 people to depend on water the source of which is 200 miles away, with all the chances of the supply being cut off taken into consideration? Dr. Hawksley says, if you will only renounce the water-closet system for the disposal of sewage, and use earth pans, you may secure the following advantages:—You may keep your present supply of water—which, if only left alone, is not so bad after all—use the sewers as waste water pipes only; breathe a purer air; return to the agriculturist the materials that by neglect of such return cause the comparative barrenness of our fields—not at the cost of 8,000,000*l.*, but making a handsome profit by such economy of material. Every one who can appreciate a philosophical and well-arranged scheme, carried into the smallest detail, should read Dr. Hawksley's book.

If the sewage is once disposed of in a rational manner, we may then, and not till then, set about securing the best water close at hand. Mr. Telford Macneill† is a good authority to follow here, but we have not space to follow him far now; but among the questions proposed are: If 200,000,000 gallons are required now, how much will be required in ten years' time, before which the most sanguine could not expect the large plans to be made available, and should not any scheme at a moderate view set this question at rest for twenty years more? The population of London, with the suburbs, at the present rate of increase, will then have reached nearly 6,000,000, requiring 400,000,000 gallons daily. Again, the author reminds us that, when the supply was improved from 1850 to 1856, the daily consumption was doubled. "Must London, then, look to both sources for its future demand? My answer is that the Thames, by the means and combinations to be described, will give an almost unlimited quantity, and of pure quality, without injury to the river or annoyance to its inhabitants." The Bagshot Sands are then proposed as a natural filtering ground for the water of the area of the basin drained by the Thames above Teddington Lock of 2,500,000 acres, with a rainfall of twenty-five inches per annum, the introduction of sewage being provided against by a very feasible scheme. The plan will be effectual without any attempt to alter the present condition of the Thames. The supply so obtained during droughts would be 800,000,000 gallons daily, close at hand. Quantity is so far satisfactorily accounted for.

As regards quality the scheme is most promising; the mean of the river and spring water will be eight and a half degrees of hardness, and two degrees of this will be lost in the passage, with a fall to prevent organic life (we would suggest the more abrupt the better for oxidation and arrest of development), and lastly, and most important of all, by percolation through an extended area, uniformity of temperature will result. For details we refer our readers to Mr. Macneill's paper. It will be seen that by this scheme we are brought to the plan so approved by the commissioners in 1851, and rejected on account of defect in quantity, the Farnham area being included in that of the proposed scheme; but the Watford basin, we must add, was preferred by them.

In reviewing thus the whole matter, we would depre-

† "Water Supply of London, by means of Natural Filtration of the Waters of the River Thames," by Telford Macneill. London: Edward Stanford, 6, Charing Cross, S.W. 1866.

cate the adoption of any scheme that possesses mainly a feature of novelty, or an opportunity for extensive engineering works, and would urge upon the commission about to discuss the question the lessons taught by a long experience, and the clear principles laid down by commissioners not less able than themselves.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On the Freezing of Aerated Waters, by Charles Tomlinson, *F.C.S.*

Priestley was, I think, the first who impregnated water with carbonic acid, so as to resemble Pyrmont or Selzer water, and he recommended brewers and distillers to employ the gas of their fermenting tuns in the manufacture of such water. This was about the year 1767. When he found that fixed air could be liberated from chalk or marble by the action of oil of vitriol, he contrived a simple but effective apparatus for impregnating water with its own bulk of the gas, and he even recommended the use of a condensing engine for impregnating the water more highly. Priestley must therefore be considered as the inventor of soda water. He attempted to impregnate ice with carbonic acid, but failed to do so. He then exposed a quantity of the impregnated water to the action of a freezing mixture. "This mixture instantly freezing the water that was contiguous to the sides of the glass, the air was discharged plentifully, so that I catched a considerable quantity in a bladder tied to the mouth of the phial." Another portion of the liquid was frozen, and "was almost as much like snow as ice, such a quantity of air-bubbles were contained in it, by which it was prodigiously increased in bulk." He further remarked that impregnated water frozen by natural cold and then thawed, had "the taste of common water only."*

During the recent cold weather I impregnated with carbonic acid distilled water contained in eight-ounce and other phials, which were then corked and exposed to the air at temperatures ranging between 23° and 30° F. The first action of the cold was to produce long needles of clear transparent ice, as thick as the little finger, occupying about the centre of the bottle, in some cases parallel with the sides, in others at an angle thereto. The further action of the cold was to enclose these transparent crystals in opaque ice, to thrust out the cork and break the bottle. In one case the bottom of the bottle was forced out; in others the sides were cracked, and the cracks ran in lines from top to bottom, nearly parallel with the long axis of the bottle. Opaque ice filled the neck, and even overflowed, so that the ejection of the cork, the fracture of the bottle, and the overflow of the ice, were simultaneous acts.

On mentioning these results to my friend Professor Miller, he advised me to try the effects of a low temperature on a bottle of soda water. Accordingly, two bottles of soda water, A and B, were taken. A was put into a jug containing a freezing mixture of snow and salt. In the course of a few minutes the soda water froze into a perfectly opaque dead-white mass. B was suspended just outside my laboratory window in an atmosphere at 28°. In the course of three-quarters of an hour long straight crystals of transparent ice passed from just below the neck to near the bottom of the bottle. In the course of another hour amorphous opaque ice began to form in the neck, and during the night this extended downwards, completely enclosing the transparent crystals (doubtless of pure water), so that the bottle, in the morning, was not to be distinguished in appearance from A.

Both bottles were now brought into the room, which was at 37°. In both a ring of ice had formed round the cork from the escape of some of the liquid from within. In both there was a feeble escape of gas, which soon increased so as to form an audible hiss. In both the corks were strained and distorted, and in A the cork had burst the wire, so that it was held apparently by the string only. On cutting the string it was found that the cork was frozen to the ice in the bottle. The ice had in both bottles slowly and quietly lifted up the cork a little, and compressed it so as to allow escape to some liquid and a constant escape to the gas—in fact, the expansion of the liquid in freezing, instead of bursting the bottle, found a line of least resistance by compressing the cork.

On watching the process of thawing, the opaque ice impregnated with gas was the first to liquefy, but the transparent crystals had become so penetrated by the opaque ice that they could not be made out during the thawing.

At the shop where I got the soda water most of the stock was frozen. I found that where transparent crystals only were formed, these could be soon thawed, and the soda water was not much, if at all, injured; but in all cases where opaque ice had formed the cork had been raised, and there was an escape of gas. On exposing the soda water a second time to the air at 26°, it froze into a vitreous mass of transparent ice; and yet there was a good deal of gas left in the water, for on testing it with lime water the precipitate was immediately taken up, and the solution became clear.

It may be worthy of remark that corked bottles of water impregnated with carbonic acid may be left on the ground during many hours exposed to a temperature of 24° without freezing. In one such case the bottle was shaken violently, but the water remained liquid. On removing the cork, however, fan-shaped crystals of opaque ice diverged from the surface of the water, and these were met by other radiating masses of crystals, so that in a few seconds the water became converted into nearly opaque ice; the bottle was not broken. A small phial of impregnated water was frozen at 24° into opaque ice without being broken or having the cork removed.

As nitrous oxide is more soluble in cold water than carbonic acid, I impregnated with that gas distilled water contained in two eight-ounce phials A B, and also in an open beaker C, of the capacity of about a pint. All three vessels were placed on the ground at the temperature of 26°. After an hour's exposure there was no appearance of freezing. In another fifteen minutes the surface of C was covered with scanty lines of transparent ice. A also contained a few long, thin, serrated crystals of transparent ice, extending the whole length of the phial. There was also a delicate icy foliage on the inner surface of the phial, following the slight projecting lines formed on the surface in the process of manufacture; the ice behaving as camphor vapour does when a bottle containing a lump of camphor is left on the window pane. The water in B was quite unfrozen; agitation and the removal of the cork had no effect. In the course of another hour the beaker displayed icy foliage on the inner surface, and

* "Experiments on Air." 1790. Vol. i. p. 120.

short crystals like grass shot up from the bottom. There was little or no change in A and B during two hours more. The vessels were left at 11 p.m., and next morning (the thermometer marked 24°) A and B were frozen and broken; C was also frozen, but not broken. In all these cases there was this difference as compared with the carbonic acid water. The centre remained unfrozen, so that on inverting the bottles a large bubble of gas ascended through a column of liquid. In the case of the beaker the central fluid portion was spherical, and from the surface of the sphere proceeded radially, large pyriform bubbles of gas, with the bulbs all directed to the centre. On showing this to Mr. Wetherell, the well known palæontologist, he pointed out the striking resemblance of this figure to some of the sea anemones. There was a layer of opaque ice above this figure, and the surface was bounded by a layer of transparent ice. The central liquid portion appeared to be a strong solution of the gas, for on taking the vessels into a warm room bubbles were liberated from it.

Highgate, January 28.

On the Analysis of Apatite—$3(3\,CaOPO_5) + CaCl$, or $(CaFl)$, *by* F. Wöhler, *Professor of Chemistry in the University of Göttingen.*

To estimate the chlorine, dissolve a known weight of the mineral, not pulverised, in dilute nitric acid,* and precipitate the chlorine with nitrate of silver.

Some kinds of apatite contain a small quantity of fluorine. When it is desired to ascertain the presence of this body, finely powder the mineral, and then mix it in a platinum crucible with concentrated sulphuric acid, covered over with a piece of glass, coated with wax and having characters traced on it with the point of a needle. Then heat the crucible, taking care not to melt the wax. If fluorine is present, the characters will be found engraved on the glass when the wax is removed. The amount of fluorine present may be deduced from the loss of weight obtained in the complete analysis. (This will be further explained in the analysis of silicates.)

The lime and phosphoric acid may be determined as in bone ash, or the following method may be employed:—Dissolve the mineral in nitric acid in a capsule, and then add pure mercury in such a quantity that when the acid is saturated with it there still remains a portion of mercury undissolved.

Evaporate the mixture on the water-bath to complete dryness. If a slight odour of nitric acid is still disengaged, add more water, and evaporate again to dryness, so as to get rid of it completely; then extract with water, place it on the smallest possible filter, and well wash the residue, which contains all the phosphoric acid.

Besides the excess of mercury the filtrate contains all the lime. With hydrochloric acid precipitate the protosalt of mercury. As a little binoxide of mercury may have been formed, precipitate the solution with ammonia. If the mineral contains iron or other bases precipitable with ammonia, these remain after calcining the last precipitate. The solution is rapidly filtered with as little exposure to the air as possible, and the lime in it precipitated with oxalate of ammonia.

The filter, which besides the excess of mercury contains phosphoric acid, is well dried, and the whole is placed in a platinum crucible and mixed with carbonate of potash and soda. The crucible is then heated to a temperature below redness, under a chimney with a good draught, until all the mercury is volatilised, after which it may be heated to redness and the contents fused. Then dissolve in water, add an excess of hydrochloric acid, and precipitate the phosphoric acid with ammonia and sulphate of magnesia.

* Certain brown apatites leave as a residue a small quantity of a crystalline powder which is cryptolite (phosphate of protoxide of cerium).

On a New Maroon Pigment, by William Skey, *Analyst to the Geological Survey, New Zealand.*

The blood-red compound obtained by adding a soluble sulphocyanide to a salt of iron in solution can be made (apparently at least) to combine with resin in the following manner:—

To concentrated solution of sesquichloride of iron and sulphocyanide of potassium in ether an etherial solution of common resin is added and well shaken together, then mixed with a sufficiency of water to cause a precipitate, when it will be found, after the mixture has stood a few hours, that the whole, or nearly the whole, of the red-coloured iron compound has united with the precipitated resin, forming the maroon-coloured pigment in question.

When this coloured substance is finely powdered and mixed with water, the water is not the least coloured; from whence I infer the red-coloured iron compound afforded by the mixture of the sulphocyanide of potassium with the iron salt has chemically united itself with the resin.

TECHNICAL CHEMISTRY.

On a New Process of Organic Elementary Analysis for Substances containing Chlorine, by C. M. Warren.

Organic bodies containing chlorine—and probably those also that contain bromine and iodine—may be analysed by a process analogous to that which I have already described for substances containing sulphur.*

As in that process, so also in this, the substance is burnt in a stream of oxygen gas, in the manner described in my first paper, "*On Organic Elementary Analysis.*"†

Similarly, also, as in the analysis of sulphur compounds, the chlorine is absorbed and retained during the combustion, by a suitable substance placed in the anterior end of the combustion tube; this substance being subsequently removed, and the chlorine determined therefrom in the usual manner. The carbon and hydrogen, in either process, are determined from the same portion of the substance as the sulphur or chlorine, in a manner similar in other respects to that described for simple hydrocarbons.‡

In pursuing this research some difficulty was experienced, as was anticipated, in finding a substance which would absorb and retain the whole of the chlorine, under conditions that would at the same time insure that every trace of the carbonic acid and water should pass through unabsorbed.

The search for this substance was confined to the oxides of the heavy metals, as these alone, from their strong affinity for chlorine and weak affinity for carbonic acid, seemed to give encouragement of success.

The difficulty, however, in finding such a substance

† *Proceedings of the American Academy*, 1864, p. 251; *American Journal of Science and Arts*, 1864, xxxviii. 387.

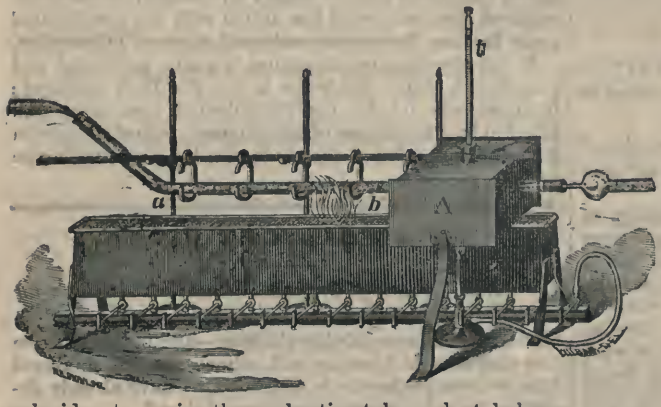
‡ *Loc. cit.*

was chiefly due to the circumstance that most of the chlorides of these metals are either too volatile, or begin to suffer decomposition at too low a temperature; it being requisite that the absorbing substance, and the newly formed chloride of the same, should bear to be heated sufficiently to prevent both condensation of water and absorption of carbonic acid, and at the same time avoid a temperature high enough to occasion any appreciable decomposition of the chloride.

This question of temperature became, therefore, a prominent one in the investigation, as evidently the success of the process must depend, in a great degree, on the proper management of the temperature of the absorbing substance, within such limits as might be found to give satisfactory results. Hence, my first step was to devise means to secure the necessary control of the temperature of that part of the combustion tube which should contain this substance.

For this purpose was constructed a sheet-iron air-bath or chamber, A, Fig. 1, provided with two holes—one in

Fig. 1.



each side—to receive the combustion tube, and a tubulure in the top for a thermometer. One end of the air-bath is made to rest on the combustion furnace, and the other, which projects a few inches from the front of the furnace to make room for a lamp, is supported by a leg resting upon the table. The bulb of the thermometer is placed in a central position, in the interior of the bath, close by the side of the combustion tube.

The temperature of the air-bath, and consequently of the substance contained in the combustion tube within, is easily regulated by means of a Bunsen's burner placed under the front end of the bath, as shown in Fig. 1. With the exception of the air-bath, the apparatus employed is the same as that used in the analysis of substances containing sulphur, a full description of which is given in the papers above referred to.

The substance that I have found best adapted to absorb the chlorine, for substances easily combustible, is brown oxide of copper, prepared by precipitation with potassa, and ignition over a gas flame.

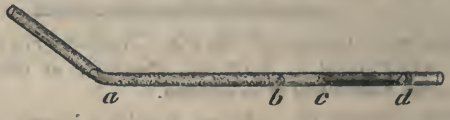
Difficultly combustible substances, like chloroform, are not completely burnt in oxygen in contact with asbestos alone, but require the presence of a body having an affinity for chlorine; otherwise there is formed a liquid body, difficultly volatile, probably a chloride of carbon, which condenses in the vacant part of the tube, from *b* to *c*, Fig. 2, and which cannot be entirely burnt off, and save the analysis. In such cases the absorbing substance is mixed with the asbestos occupying the back part of the tube, where the combustion takes place. It is evident that oxide of copper would not answer for this purpose, as at so high a temperature dichloride of copper would be formed, which, being insoluble in dilute acids, would interfere with the determination of the chlorine. Oxide of zinc has been found to give good results with such substances.

The preparation of the combustion tube, and the arrangement of the mixture of asbestos and the absorbing substance, is the same—except in the case last mentioned—as in the analysis of substances containing sulphur, as shown in Fig. 2—viz., the space between *a* and *b*, about ten inches in length, is packed with pure asbestos; between *b* and *c*—a space of about two inches—being left vacant, a plug of asbestos is placed at *c*; the space between *c* and *d*, four to five inches in length, is filled with an intimate mixture of asbestos and brown oxide of copper; and, finally, a plug of asbestos is placed at *d*.

After the combustion, the chloride, together with the excess of oxide, is extracted from the asbestos by means of dilute nitric acid.

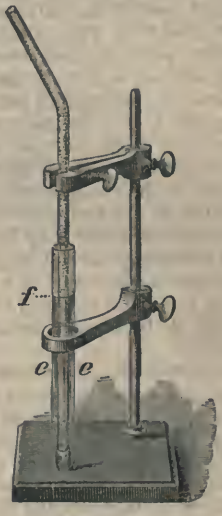
To facilitate the removal of what may adhere to the

Fig. 2.



sides of the tube, the apparatus shown in Fig. 3 will be found serviceable, as in the analysis of sulphur compounds.

Fig. 3.



(To be continued.)

What is a "Professor?"—"The term *professor* is sometimes put very prominently before us as one of superior distinction—a still larger handle to the name. We have, however, professors of hair cutting, of carpet shaking, of dancing, and of the 'noble art of self-defence,' as well as of medicine or surgery; and if we may judge of the public appreciation of the term by the use made of it in the newspapers, it has a much wider significance than that of men of learning or science appointed to the office of teachers by incorporated colleges, which is its technical definition."—*A Discourse on Titles, &c., by Edward Parrish, Philadelphia.*

PHARMACY, TOXICOLOGY, &c.

On the Preparation of Medical Tinctures, by M.* FILHOL.

THE various writers on the preparation of medical tinctures have given most of their attention to the best method of exhausting substances submitted to the action of a solvent (alcohol, ether, &c.). Two methods have been proposed. The first consists in macerating the substances properly divided for a sufficient time in the liquid which is to produce the tincture, and filtering and submitting the residue to sufficient pressure to extract the portion of tincture it retains. The second, known as the displacement method, consists in submitting the substance destined to undergo the action of a solvent to a methodical washing and displacing the tincture remaining in the powder by water, or by alcohol when an alcoholic tincture is desired.

It is generally admitted that the latter method produces in a very short time a tincture quite as rich, sometimes even richer, in soluble material than that obtained from the same substances by prolonged maceration. But it is undeniable that those prepared by maceration keep better, and are less apt to become turbid, than those prepared by the second method. On the other hand, it seems impossible to displace alcohol by water, for the two liquids mix in an appreciable manner, and little economy can result from this plan. The maceration process seems then to be the best.

I will not here enter into all that has been said for and against each of these methods, but will merely observe that the question does not appear to me to have been hitherto studied in a manner which is alone calculated to remove all doubts.

It would, in fact, be of little consequence that tinctures prepared by the displacement method should, after a few days, furnish a slight deposit, were it proved that the substance forming this deposit was inert, and that its preparation did not lessen the value of the medicine. It would be quite the reverse were this deposit formed essentially of principles possessing great activity. This, then, is a point which it was necessary should be cleared up by a series of consistent researches and qualitative analysis, executed with all possible care and precision.

It is important, also, in estimating the value of the tinctures, not to rely solely on their relative densities, or on the quantity of dry residue left by evaporation, but rather on the results of the analyses of these residues, for it sometimes happens that the best tincture gives the least residue, being richer in alkaloids and other really active principles than those giving the smaller quantity of residue. I am aware that the researches I have indicated would require much time and skill on the part of the operator, but there are many druggists capable of successfully undertaking them.

One word more concerning tinctures.

In my opinion, alcohol is not so good a preservative as it is generally supposed to be, and the tinctures should be used as soon as possible after they are prepared. The following facts prove that certain immediate principles of vegetable origin alter when dissolved in alcohol.

A tincture prepared from the leaves of a plant will be of a beautiful green colour, due to the presence of chlorophyl, and will, under the influence of hydrochloric acid, undergo transformations, which M. Frémy has described, and which I have studied myself. Now, these transformations do not take place in a tincture which has been prepared for several months, and the most essential characteristics of chlorophyl disappear.

The petals of the ranunculus, macerated in alcohol, give a golden yellow tincture, which, on the addition of an equal volume of hydrochloric acid, turns green. After the liquid has been filtered, a yellow substance remains on the paper, and the filtered liquid is of a pure blue colour. Nothing of this kind takes place when the tincture has been kept some time. Then the liquid remains yellow in spite of the addition of hydrochloric acid. In this case the xanthine of the flowers has been altered, as well as the chlorophyl.

Attentive study will probably lead to the discovery that other matters also undergo great alteration.

Now it is certain that tinctures, possessing all the properties I have mentioned, can be prepared from leaves or flowers well dried and kept from air and light during several months. It is therefore better to preserve the plants than the tinctures, and the latter should, as I have said, be prepared in small quantities, and used as fresh as possible.

FOREIGN SCIENCE.

(FROM OUR OWN CORRESPONDENT.)

PARIS, February 5, 1867.

THE Council of the French Photographic Society, whose establishment is at 9, Rue Cadet, has taken the following resolution, and thus shows a very good example, which will be, we hope, imitated. All the French and foreign strangers admitted to the Exhibition will have admittance to the saloons of the Society and will be able to attend the meetings. A personal card will be delivered to them at the Secretary's office of the Society. Besides the usual meeting held the first Friday in each month, the Society will meet on the third Friday either for a general meeting or to hear a lecture on subjects interesting to photography. The ordinary recess of the Society, which habitually takes place in the month of August, will be this year postponed to the months of October and November.

At the demand of M. Regnault, the illustrious chemist and physicist, president of the Photographic Society, the Parisian Gas Company has decided to manufacture on a large scale alkaline sulphocyanides, and especially the sulphocyanide of sodium. The price fixed by the Company is 3 frs. the kilogramme. Thanks to this decision, the introduction of sulphocyanides into photographic consumption is henceforth assured, for the Company can produce 60 tons of them annually.

Heliographic engraving, or the production by means of photography of proofs which can be printed from, either by copper-plate or lithographic impression, by a thick ink or by carbon, has made this year in France and England a really wonderful progress. On Friday, the 2nd inst., M. Baldus presented to the Photographic Society three long series of proofs, taken from ancient engravings or from nature, which excited universal admiration. In fact, nothing could be seen more beautiful than the reproduction by this process of the celebrated engravings by Mark Anthony, after Raphael. M. Baldus did not explain his process, for this principal reason, that it is so simple that one would scarcely believe it. Moreover, it is a process perfectly industrial, and of which the products can be given at a fabulously low price. For us who are acquainted with the phototypes in carbon or thick inks of Messrs. Woodbury, Swan, &c., we do not hesitate to declare that M. Baldus leaves them very far behind him. We can compare his proofs only to the heliographic engraving of M. Garnier.

MM. Camille Saint-Pierre and Pugo, Professors of the Faculty of Montpellier, with regard to the question of taking the density of wines, have made some very conscientious researches upon the densities of the wines of the Department of L'Herault, of which the following are the results. They are interesting, to a certain point, to England, to which country a great deal of wine is exported from Cette. The density of the red wines of L'Herault differs but little from that of water; the weight of 1000 litres of wine varies from 994 to 999 kilogrammes. The dry white wines are generally a little lighter than the red wines; 1000 litres weigh from 991 to 994 kilogrammes. As to sweet wines, which comprise muscatel and liqueur wines, notwithstanding the quantity of alcohol they contain, which tends to lower their density, they have a specific gravity greater than that of water, owing to the great quantity of sugar they contain. Vinegars are heavier than the wines from which they are obtained. To sell, then, white and red wines by weight does not expose one to a sensible error in commercial transactions. With regard to sweet wines, there is generally sufficient difference between their densities and that of water; so that, in the substitution of the sale by weight instead of by measure, the relation of the weight to the volume should be taken into account. The measuring of wine is a very costly process; it takes up much time, and is at the same time very inexact. There will be great advantages in abandoning it and adopting the sale by weight.

M. Stephan, Director of the Observatory at Marseilles—a supplementary one to the Imperial Observatory of Paris—discovered in the night of Tuesday, January 22, a new comet, of which he could only determine the position on the 25th.

Mean time at Marseilles, January 25 . 8h. 53m. 35s.
Right ascension of the comet . . 2h. 33m. 53·58.
North Polar distance . . . . 74° 26′.
Hourly movement: in right ascension +5′17s.; in Polar distance −1·29′.

The comet is rather brilliant, in appearance generally round, with a well-defined nucleus; it appears denser at one side than the other, so as to lead to the supposition that the tail is fan-shaped. The apparition of a comet after the excellent researches of Messrs. Huggins and Miller on spectral analysis, is a fortunate event that must be at once announced, so as not to lose any chance of observation; and we find it very extraordinary that M. Le Verrier did not give any particulars of the new comet before the bulletin of the Observatory, dated February 1. No. 1625 of the *Astronomische Nachrichten*, published on January 30, does not say a word about the comet.

The "Florentin" diamond—such is the name given to a jewel in the possession of the Imperial Treasury at Vienna. It is of the first water, and is mentioned in all the books on precious stones as weighing 139¼ carats, or 2¾ carats more than the "Regent," worn by the Empress of the French, and 54½ carats less than the "Orlof" of the Russian regalia. The inventory of the Imperial Treasury of Austria gives its weight as 133½ carats. A commission convoked for this purpose has recently ascertained, by means of an extremely delicate balance, that this diamond weighs 27·454 grammes = 133·185 carats of Vienna = 133·600 carats of Paris = 139·20 carats of Florence, and that at a temperature of 19° C. its density was to that of water in the ratio of 3·5213 to 1·000. Dr. Hörnes, director of the Imperial Museum of Mineralogy, and member of the above-named commission, has taken a plaster cast of the "Florentin," so as to serve as a model for a copy in crystal glass, representing exactly the bulk, shape, and tint* of the original. The value of this diamond, according to the usual commercial rules of calculation, amounts to two and a half millions of florins, or about 250,000*l*.

* Our Vienna correspondent has not given the colour of this celebrated diamond.—F. M.

MM. J. Vavin and G. Fribourg have invented an automatic electro-chemical method of electric transmission of despatches, with a view of utilising all the velocity of the current on telegraphic lines. It consists in the distribution of the current through as many small wires very short and isolated as there are signals to be transmitted, all the while only employing one wire on the main line. Each of these small isolated wires communicates on the one hand with a metallic plate of a particular form fixed in gutta-percha, and on the other hand with a metallic division of a disc, which is equally formed of an insulating substance. A group of eleven of these small laminæ form a sort of character which will give all the letters of the alphabet by the suppression of certain portions of the fundamental form. Now, suppose rows of these compound characters to be placed on a sheet of prepared paper of a metallic nature, the words of the telegram to be sent are written on them with isolating ink, leaving the other parts of the small "stereotyped" blocks untouched. The consequence is that the current is intercepted at every point touched by the ink, and a letter is imprinted on the prepared paper at the other end of the line where the telegram is to be received. It is hard to explain the system without an illustration; yet, if the invention meets the encouragement it deserves and works well, we shall return to the subject and give an illustration.

M. E. Arnoux, chef d'escadron of the French Marine Artillery, has proposed a new arrangement in the telegraphic service, the aim of which is to popularise and extend the use of the telegraph. For this purpose he deems it necessary to—

1. Guarantee the secresy of the despatches in the same way as of letters by post.
2. To lower the rate of telegraphic messages, so as to place them on a rational and equitable footing.
3. Lastly, to increase considerably the number of transmissions, at the same time augmenting as little as possible the number of assistants and the apparatus in use.

The author (and perhaps justly) exclaims against routine, and wishes for reform. He says:—"*Non seulement la routine conserve scrupuleusement comme un dépôt sacré les vieilles erreurs, mais elle s'oppose encore de toutes ses forces aux améliorations les plus legitimes,*" &c., &c.

The immense success of the lighting up of the ball *fête* of the skaters at the Bois de Boulogne caused his Majesty the Emperor of the French to make a trial again of the electric light for illuminating the courts of the Tuileries and the Carousel. On Saturday, February 2, M. Serrin was invited to place two of his lamps on the Arc de Triomphe of the Place du Carousel. The light being enclosed in two ellipsoidal enamelled urns, made by M. Paris, was not only unfatiguing to the eye, but it was contemplated with pleasure. Two electric burners are evidently too few for this immense space, and yet it was entirely lit up. In the interior of the court of the Tuileries the light was better than that of all the gaslights; on the Place du Carousel the gas was nearly all eclipsed. The continuity and fixity of the light were truly astonishing. When, according to the adopted project, the iron railing forming the present enclosure of the courtyard of the Tuileries is advanced as far as the middle of the Place, four or six lamps lit by electricity, and placed above the railing, will furnish an illumination the most splendid, inoffensive, and economical that can be imagined. It seems to us impossible that they will hesitate a moment in adopting it, the more so as the actual mode of illuminating the *two Places* is so inefficient that they are truly plunged in obscurity.

The electric telegraph makes wonderful strides every day. On the 2nd instant we saw, at the Central Office of the Direction of Telegraphs, a simple dial telegraph, invented by M. Alphonse Joly, special agent of the Administration of Telegraphs, work wonders. Through a length of 250 kilometres it prints, at the same time, very rapidly, letters,

figures, and all signs of punctuation, &c. We shall not be much surprised to see this instrument become universal. Without being as rapid as that of Hughes, the *chef d'œuvre* of ingenuity, but which requires a practised hand to work it, and is well adapted for great lines of communication, the telegraph of M. Joly, which prints at once the despatch both at the transmitting and receiving offices, can give from two to three letters per second, from 120 to 180 per minute, a despatch of more than twenty words at the rate of sixty despatches per hour—a velocity sufficient for all secondary lines.

F. Moigno.

PROCEEDINGS OF SOCIETIES.

ROYAL INSTITUTION OF GREAT BRITAIN.

Owing to the indisposition of Professor Max Müller, on Friday, February 1, his lecture "*On the Language and Antiquities of Cornwall*" was not delivered, and Mr. Scott Russell supplied his place by an interesting lecture upon "*The Late Fire at the Crystal Palace.*" The lecturer divided his subject into three parts—viz., the construction of the building, the fire, and the measures to be taken to remedy the mischief done. The Crystal Palace, as every one knows, is the offspring of the Great Exhibition of 1851, the idea of which undoubtedly belongs in the first instance to the late Prince Consort. After giving some very interesting details as to Sir J. Paxton's original design, and the improvements that were eventually adopted, Mr. Russell proceeded to describe the plan of the construction, which, while giving immense strength, procured that appearance of lightness and elegance which is so marked a feature of the present building. The most essential point is the arrangement of the supporting columns, which are eight inches in diameter and twenty feet long, and the ends of each of which are joined to those of its neighbour by what is known to engineers as a triangular truss girder. In this way each set of four pillars represent the legs of a table, and are kept in position by the girders which form the sides. The whole building is simply a collection of these tables and legs, each one adding strength to all the others, so that any strain on one part is resisted by the combined strength of the whole.

The lecturer, after explaining how the present Crystal Palace grew out of the Exhibition, proceeded to give an account of the fire. The facts are as follows:—There was no fire at 2 o'clock on Sunday afternoon. The fire was first noticed at a period given by different observers at from 5 to 20 minutes past 2. Mr. Russell arrived at the Palace at 10 minutes to 3, at which time the north transept was in a blaze. Seeing at once it was useless to attempt to extinguish the flames, he procured assistance and succeeded in preventing them spreading, being helped towards the last by the London fire-engines. The flames, says Mr. Russell, died away with a celerity that was perfectly marvellous.

The origin of the fire is still very doubtful. The lecturer suggests the following hypothesis:—The tropical department was warmed by pipes supplied from a large boiler underneath the flooring towards the east end of the north transept, and near to where the bark of the large tree was standing. The fireman attending to this boiler banked up his fire, and left it for some hours in the morning. Now, as chemists are aware, the result of putting a large quantity of coal on to a small fire is to generate inflammable gas. This, it is thought, actually took place; the gas found a convenient chimney provided by the skeleton tree, and when a large amount had been produced it caught fire, and immediately became a mass of flame. The building itself, Mr. Russell states, is quite fireproof—that is to say, it will neither burn nor communicate flame, but of course is liable to be injured or destroyed by the burning of combustibles inside it. This is shown by the rapidity with which the flames died out when they were once checked.

The question of what had better be done Mr. Russell decides in a very few words. The Crystal Palace is a great educational work, and as such deserves, and in other countries would receive, the support of the Government. But here the Government does not interfere in these matters. We are proud of being ourselves the government in most respects, and should therefore take upon ourselves the duty of a government in this matter, and by a sufficient subscription preserve this great institution to the nation, with all its original usefulness and beauty unimpaired.

GEOLOGICAL SOCIETY.

At the last meeting of the Geological Society of London, George Maw, Esq., F.G.S., F.L.S., &c., read some "*Notes on some Chemical Analyses of Variegated Strata.*" The author gave the results of some analyses for the determination of iron in the light and dark parts of variegated slates, sandstones, and marls, the colour of which is due to oxide of iron, and in which the variegation appears to be disposed independently of mechanical arrangement. The analysis in each case exhibited the fact that the lighter blotches, spots, and stripes contained a smaller portion of the colouring oxide than the average mass, a proportion which implies an actual difference in the percentage of the metallic iron, and which could not be accounted for by any mere difference in the state of its combination. This shows an actual departure of a part of the colouring oxide out of the colourless patches, and a dispersive process which seemed to be the very reverse of the segregation of nodules of carbonate of lime and carbonate of iron out of a clayey matrix. Among the forms of variegation referred to were: (1st) that resulting from the segregation of dark blotches out of a lighter matrix, the evenness of colour of which does not appear to have been materially affected by the withdrawal of a part of its colouring matter; (2nd) that resulting from the segregation of dark blotches out of a lighter ground, each of which is concentrically surrounded by a distinct and well-defined zone lighter than the general ground; (3rd) strata variegated with light blotches containing a smaller proportion of colouring matter than the general ground, but not arranged concentrically round a darker nucleus; (4th) the variegation of coloured strata with both light and dark blotches, containing respectively a smaller and larger proportion of the colouring oxide than the general ground, but which are not arranged, as in the second case, concentrically with each other.

MANCHESTER LITERARY AND PHILOSOPHICAL SOCIETY.

Ordinary Meeting, January 8, 1867.

Edward Schunck, *Ph.D., F.R.S., President, in the Chair.*

Mr. Binney, F.R.S., F.G.S., exhibited two remarkable fossils discovered by Mr. Joseph Tindall, of Thomas Street, Huddersfield, in the lower coal measures near that town.

The following papers were read:—"*On the amount of Carbonic Acid contained in Sea Air,*" by T. E. Thorpe (Dalton Scholar in the Laboratory of Owen's College), communicated by Professor H. E. Roscoe, F.R.S., &c. The main conclusions to be drawn from this paper may be briefly stated as follows:—1. That the sea does not act in increasing the amount of atmospheric carbonic acid. 2. But that, on the contrary, the air over the sea contains a much smaller proportion of carbonic acid than the air of the land, although the influence of the sea in abstracting

this gas from the atmosphere is not so great as the observations of Vogel and Krüger would indicate. 3. That the mean quantity of carbonic acid gas contained in the normal atmosphere of the ocean is 3·00 in 10,000 volumes of air. 4. That the proportion is constant, or nearly so, in different latitudes. 5. That this proportion is not sensibly influenced by the different seasons of the year. 6. That this proportion does not experience any perceptible diurnal variation.

"*On the amount of Carbonic Acid contained in the Atmosphere of Tropical Brazils during the Rainy Season,*" by T. E. Thorpe. From thirty-one experiments it appears that the mean quantity of carbonic acid contained in the air of tropical Brazils during the months of April and May, 1866, was 3·28 in 10,000 volumes of air—a decided difference from the mean proportion (4·0 vols. in 10,000 of air) contained in the atmosphere of Europe, and probably due in great measure to the joint action of tropical rain and tropical vegetation in withdrawing this gas from the air.

PHYSICAL AND MATHEMATICAL SECTION.

November 8, 1866.

E. W. Binney, *F.R.S., F.G.S., President of the Section, in the Chair.*

Mr. Baxendell, F.R.A.S., read a paper entitled "*Observations of the New Variable Star T Coronæ.*"

Mr. Brothers, F.R.A.S., communicated an appendix to his "*Catalogue of Binary Stars*" presented to the section at its last meeting.

December 6, 1866.

E. W. Binney, *F.R.S., F.G.S., President of the Section, in the Chair.*

Mr. Heelis, F.R.A.S., exhibited some drawings of a hydraulic clock which he had made for the purpose of driving his Equatorial, and described the nature of its action and adjustment, the principal feature being that of using the same water over and over again.

Mr. Brothers, F.R.A.S., communicated an "*Observation of the Occultation of Aldebaran,*" which took place on the 22nd ult.

Mr. Heelis, F.R.A.S., read a paper "*On some Recent Results of Observations of the Specific Gravity of Sea Water.*"

January 3, 1867.

E. W. Binney, *F.R.S., F.G.S., President of the Section, in the Chair.*

"*On the Mean Weekly Temperature at Old Trafford, Manchester, for the Seventeen Years* 1850-1866," by G. V. Vernon, F.R.A.S., F.M.S.

"*On the Rainfall for* 1866 *at Old Trafford, Manchester,*" by G. V. Vernon, F.R.A.S., F.M.S.

"*Results of Observations of Variable Stars made at the Mannheim Observatory during the Year* 1866," by Dr. E. Schönfeld, Director of the Observatory.

PHOTOGRAPHICAL SECTION.

January 10, 1867.

Dr. J. P. Joule, *F.R.S., &c., Vice-President of the Section, in the Chair.*

Mr. Coote exhibited a selection from the series of photographs by Braun, of Paris, consisting of copies of drawings by the old masters from the originals in the Louvre. Mr. Coote explained the method by which they were supposed to be printed, and from the appearance of some of the prints there could be no doubt that one of the processes suggested by Sir John Herschel about the year 1840, or some modification, had been employed; and it was evident that the method proposed by Mr. Gatty would also produce similar results. The prints are remarkable for their perfect resemblance to old drawings and sketches, and, as studies for artists and for use in schools of design, are quite equal to the originals. Of their permanence there cannot be the least doubt.

The following letters from Mr. J. B. Dancer, F.R.A.S., addressed to the Chairman, were then read by the Secretary:—

"1. I am too unwell to attend the meeting of the Section this evening, and have therefore put on paper a few remarks on 'Braun's' copies of drawings of the old masters.

"Mr. Coote kindly showed me these pictures, and my first impression was, that they had been produced by Mr. Swan's process, as it is quite possible to replace the carbon by coloured pigments, and imitate the colour of any chalk, crayon, or even black lead pencil, in the latter case using plumbago. The act of rolling a picture of this kind would give it a lustre like a pencil drawing. There are specimens of this appearance in the collection.

"Having had occasion to write to Mr. Swan, I requested him to give me such information as he possessed as to how these copies were produced. The following is an extract from his reply:—

"'*To J. B. Dancer.*

"'Many thanks for your kind inquiry. Mr. Braun, of Dornach, is printing a number of copies of pictures by my process, in particular a series of Holbein's works; and if this series form a part of the collection to be exhibited at your Society's meeting, they are no doubt by my process. Mr. Braun is, however, also using another process (Rousseau's) for the production of the Louvre pictures, and I think it most probable that all the red pictures, except the Holbeins, are by this process. I do not know precisely what M. Rousseau's process is, but I have heard that it is a modification of one of the processes of Sir John Herschel.

"'You are quite right in thinking my process suitable for the imitation of old red chalk drawings; the shades of colour can be imitated exactly.

"'Mr. Braun is now carrying out my process very energetically, and has erected a steam engine to drive the tissue-making machinery. "'Joseph W. Swan.'

"I think, Mr. Chairman, you will agree with me, when looking over these copies, that they mark a most important advancement in the art of photography. In these productions we have identity in colour as well as in form.

"2. At a meeting of the Photographical Section, October 4, 1866, it may be remembered that I exhibited some specimens of photographs in various colours on paper and calico, a process invented by Mr. John Mercer, F.R.S. I did not recollect sufficient of what Mr. Mercer had told me of the process to give you any definite information as to the production of the colours. A few days since I stumbled on his description; if it is thought of sufficient interest, please to communicate it to the members.

"Mr. Mercer read a paper on the subject at the meeting of the British Association at Leeds in the year 1858. He exhibited coloured photographs on paper and calico, and gave the following directions for producing them:—

"*Directions.*

"34 oz. of sulphate of iron are converted into peroxalate; this is diluted to 2 gallons, and will impregnate 200 square yards of paper. The paper being floated on the solution until fully wet in the usual way, it is then exposed, and afterwards steeped in some solution which only acts on that part where the iron has been reduced from the per- to the protoxide. Red prussiate of potash and sulphuric acid act well, making the image blue and the ground white.

"Sulphocyanide of potassium and a salt of copper form another bath; the protoxide of the picture deoxodises the copper, and the sulphocyanide of the suboxide of copper is fixed in the cambric or paper. This may be converted into the red prussiate of copper.

"A vast number of colours may be obtained by replacing the iron or copper by other metals, such as lead, zinc, tin, mercury, silver, gold, or manganese.

"With these bases may be used various dyes, as madder,

cochineal, murexide, logwood, galls, or quercitron bark, besides the iodides, chromates, prussiates, or oxides of the metals themselves and mixtures of these.

"He also showed how the peroxalate paper might be used as a fair actinometer, by placing a slip between the leaves of a book and pulling it out by steps every stated number of seconds. It is then easily converted into a graduated scale."

NOTICES OF BOOKS.

Water: Its Impurities and Purification. By The London and General Water Purifying Company (Limited). London: Published at the Company's Offices, 157, Strand, W.C. 1865.

This little pamphlet points out the evils attendant upon impure water, both in economy and health, quoting the celebrated case of the Broad-street pump, and then shows that the present water supply of London is far from being so pure as could be desired. To remedy this, the Company propose to suppy filters, invented and patented by Mr. Danchell, which they undertake to furnish and fit up to the existing cisterns on the payment of a yearly rent, to keep them in working order, and to exchange when worn out. Numerous very favourable opinions as to the merits of this filter are quoted from various eminent chemists and others conversant with the subject. Mr. Danchell also supplies a testing apparatus by means of which any one may satisfy himself as to the quality of the water he is using. Considering the importance of pure water, as proved by the late visitation of cholera, we commend these matters to the consideration of our readers.

The Pill Book. By Arnold J. Cooley. London: Robert Hardwicke, 192, Piccadilly. 1866.

Of all the ills that flesh is heir to, upwards of 1050 in the shape of pills and boluses are definitely accounted for by the author of this book, whether they be Pharmacopœial, hospital, magistral, or quack. We read of Analeptic Barbarossa, Rev. D. Barclay's, (ten drugs); Arabian Anticholeraic; Female; Paullinic; Sphariopeptic, or Eli Ahmed's; Mrs. Stephen's; Sulphurated Fuligo Kali; Tobacco and Toothache pills, and others equally mysterious. Strange to say, there are no Abracadabra pills. But there are others that were favourite remedies of Dupuytren, Ricord, Sir Astley Cooper, Sir Benjamin Brodie, and Sir Charles Bell.

As a type of the curious information contained at intervals throughout the volume, we quote the following:—"Everlasting Pills.—Small spheres of metallic antimony of the size of ordinary pills; they possess the quality of purging as often as swallowed with scarcely any sensible diminution in weight. According to some of the old writers, half a dozen of these pills often served a whole family for a life-time, and were handed down as heirlooms to their children."

The weights and measures of pharmacy are most faulty, there being three distinct systems more or less in use. The avoirdupois pound is used by the Dublin and British Pharmacopœias, while the London one, still used, adopts that of the apothecaries' weight. We thus find that in one case the scruple is not recognised as a weight at all; in another it equals 18⅔ gr.; in a third it is equivalent to 20 gr. The whole system is confusing in the extreme. The only rational improvement noticed in the book is the use of granules containing known weights of compounds at the same time of great medicinal use and of fixed chemical composition. Thus, laudanum is made from a certain weight of opium, which may contain 3 or 10 per cent. of morphia, and comparative results will be recorded by different users of the drug. By a new system recommended by such men as Trousseau and Reveil, ⅛th of a grain of morphia in a granule of pure sugar would be given. So with digitaline, corrosive sublimate, or strychnia. These eminent Physicians remark that "their preservation is indefinite, their solution is always easy, and they are well adapted to supplant common pills in the administration of very active medicine. The book is what it professes to be—a *vade mecum* for pharmacists, but, we hope, not for emigrants and travellers; and we are grateful to say that we have no occasion to carry it about with us—more in its praise could not be well written.

CONTEMPORARY SCIENTIFIC PRESS.

[Under this heading it is intended to give the titles of all the chemical papers which are published in the principal scientific periodicals of the Continent. Articles which are merely reprints or abstracts of papers already noticed will be omitted. Abstracts of the more important papers here announced will appear in future numbers of the Chemical News.]

Pharmaceutische Zeitschrift für Russland. Heft 7, Jahrgang V. November, 1866.

M. Kubly "*On the Separation of the Alkaloids of Opium in Forensic Chemical Researches.*"—Adolph Fero "*On the different kinds of Rhubarb Roots now met with in Trade in Russia.*"—Glenard "*On the Mode of Estimating the Quantity of Arsenious Acid which may be met with in Magisterium Bismuthi, Subnitrate of Bismuth.*"—Wagner: "*Analytical Researches on the Fluids discharged from those Suffering from Asiatic Cholera;*" "*On the Composition of Urine in Dropsy;*" "*On the Artificial Production of Benzoic Acid.*"—Von Aldenkort "*On the Action of Caustic Potassa on Urine discharged by Persons who took a Dose of Santonine;*" "*On the Fractional Distillation of Liquids.*"—Professor Dr. H. Ludwig "*On an Intestinal Calculus of a Lama;*" "*On the Preparation of Hyoscyamine.*"—Dr. W. NOTICES OF PATENTS.

Communicated by Mr. Vaughan, F.C.S., Patent Agent, 54, Chancery Lane, W. C.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

3423. W. B. Berrey, Liverpool, Lancashire, "An improved composition for cleaning glass and other smooth and bright surfaces."

3432. G. Payne, Battersea, "Improvements in the manufacture of soap."—Petition recorded Dec. 29, 1866.

3448. W. Clark, Chancery Lane, "Improvements in the manufacture of hydrogen gas and in apparatus for the same; also in the application of the said gas for lighting and heating, and as a motive power."—December 31, 1869

Notices to Proceed.

2374. B. Bayliss, Pontnewydd, near Newport, Monmouthshire, "Improvements in the manufacture of iron."—Petition recorded Sept. 15, 1866.

2380. P. Brash, Leith, Midlothian, and W. Young, Straiton, Midlothian, "Improvements in the manufacture of oil from shale and other bituminous substances."—Sept. 17, 1866.

2450. A. F. Stoddard, Glasgow, N.B., "A new or improved fuel."

2452. J. Calvert, Strand, Middlesex, "Improvements in the treatment and manufacture of iron and steel."

2454. J. Gamgee, Queen's Road, Bayswater, Middlesex, and A. Gamgee, M.D., Alva Street, Edinburgh, "Improvements in the slaughtering of animals, with a view to the preservation of their bodies as articles of food, and in the method of preserving animal and vegetable substances."—Sept. 24, 1866.

2496. A. V. Newton, Chancery Lane, "An improvement in the process of distilling petroleum and other oils." A communication from O. Lugo and T. O. L. Schrader, New York, U.S.A.—September 27, 1866.

2568. W. G. Valentin, Royal College of Chemistry, and G. H. Benson, Staleybridge, Cheshire, "Improvements in the manufacture of steel."—October 5, 1866.

2593. G. T. Bousfield, Brixton, Surrey, "Improvements in separating sulphur from soda waste." A communication from P. W. Hofmann, Ph.D., Dienze, France.—October 8, 1866.

2612. G. H. Benson, Staleybridge, Cheshire, and W. G. Valentin, Royal College of Chemistry, "Improvements in the melting and casting of steel, and in the apparatus employed therein."

2614. G. H. Benson, Staleybridge, Cheshire, and W. G. Valentin, Royal College of Chemistry, "Improvements in the manufacture of malleable iron and steel, and in the apparatus employed in such manufacture."

2616. G. H. Benson, Staleybridge, Cheshire, and W. G. Valentin, Royal College of Chemistry, "Improvements in the manufacture of iron and steel, and in the apparatus employed therein."—October 9, 1866.

3106. W. G. Newton, Chancery Lane, "An improved process for extracting oil and paraffin from bituminous substances, such as peat or coal." A communication from S. L. Wiegand, Philadelphia, Penn., U.S.A.—November 26, 1866.

3214. J. Williamson, South Shields, "Improvements in the manufacture of alkalies."—December 6, 1866.

3311. H. Hall, Stacksteads, near Manchester, "Certain improvements in the preparation of size and in apparatus connected therewith."—December 17, 1866.

3355. A. V. Newton, Chancery Lane, "An improved compound for coating ships' bottoms and other surfaces." A communication from C. J. Eames, New York, U.S.A.—December 20, 1866.

3386. H. A. Dufrené, Rue de la Fidélité, Paris, "Certain improvements in the manufacture of the extract of madder." A communication from J. Pernod, Rue des Clés, Avignon, France.—December 24, 1866.

88. R. Mushet, Cheltenham, "An improvement in the manufacture of cast steel."—January 14, 1867.

CORRESPONDENCE.

German Yeast.

To the Editor of the Chemical News.

Sir,—Can any of your subscribers give me a ready way of examining German yeast? A friend has sent me some to examine; he complains that his children suffer from cutaneous disturbance, attributable, as he thinks, either to flour or German yeast. I am not acquainted with the probable impurities in this substance. I have examined his flour, and it is unexceptionable.

I am, &c. G. Y., Subscriber.

Clairvoyance.

To the Editor of the Chemical News.

Sir,—Any of your readers taking the trouble to refer to vol. vii., p. 279, of the Chemical News will find that Professor Wanklyn's newest discovery was accurately foretold by M. Berthelot more than thirteen years ago.

I am, &c. A Subscriber.

Commercial Analyses.

To the Editor of the Chemical News.

Sir,—Mr. Newlands seems to have somewhat mistaken the drift of my communication (page 21); for though it was certainly originated by the letter signed "A Smatterer," it did not profess to be a "reply" to it, but was intended rather to urge a couple of practical suggestions on the notice of analysts.

Surely Mr. Newlands cannot be unaware, as he would seem to imply, of the "discrepancies" (to use the mildest term) between commercial analyses, which often render them "a delusion and a snare." They are, unfortunately, matters of general notoriety, and tend greatly to shake the confidence of practical men in the resources of our science. I can cite an illustration which may, perhaps, possess some extraneous interest.

Some years ago a colliery proprietor in this neighbourhood found seams of what he conceived to be a valuable ore of iron in his coal measures. He had a cheap analysis of it from a "low" analyst of this city, who reported it to "contain 54 per cent. of iron" (the *pure* carbonate contains only 49 per cent.) However, mistrusting his good

fortune, he sent me a sample which I analysed thoroughly and carefully, with the following rather different results :—

The stone was of a dark grey colour, like limestone, and quite homogeneous. It was so hard as to give abundance of sparks under the hammer, and to be extremely difficult to grind down. It was fluxed with carbonate of soda, and the filtrate from the silicic acid reduced again by a little sulphite of soda before separating the oxide of iron and alumina by boiling with potass. As acids had little effect on it, even in the finest powder, a portion was ignited in a closed crucible till the weight became constant, and the loss was calculated for carbonic acid according to the equation—$5(FeO,CO_2)=3FeO,Fe_2O_3+4CO_2+CO$.

Protoxide of iron . . .	28·686*
Alumina	7·776
Lime	·767
Magnesia	3·693
Carbonic acid	14·610
Silica	43·932
Organic matter, &c. . .	·536
	100·000

Upon these results I reported the ore to be valueless, as, besides that the percentage of metal was low, the amount of silica would be very objectionable to the smelter. To bring the matter to a practical issue, my client sent a sample of fifty tons to Dudley, and found that the ironmasters there would only give for it two shillings per ton over and above the cost of transport. The result was, that a large quantity of the material "got" at some expense was thrown away, and the owner was quite ready to confess that the highest-priced analysis was really the cheapest. Numbers of similar cases must be known to every practised analyst.

There is one sentence in Mr. Newlands' letter which is so diverting from its ingenuous simplicity that I cannot pass it over, to wit—"A manufacturer 'of several years' experience' could not well be capable of offering to a professional man an amount which he must be well aware would not repay the latter for the necessary care and trouble bestowed on such analyses." I fancy most analysts, on reading the above and recalling their past experiences, would feel prompted to either a sad smile or a loud guffaw, according to their respective temperaments.

I am, &c. F. W. Griffin, Ph.D.

Bristol School of Chemistry.

MISCELLANEOUS.

Visitors to the Paris Exhibition. — Probably many of our readers have determined to visit Paris during the time of the International Exhibition. It may not have occurred to such, that arrangements for such visits should be made at once, beforehand, but we would press upon all the necessity of making them as soon as they can. The tradesmen and hotel-keepers of Paris are promising themselves a golden harvest, and there is little chance of any arrangement being made with them, unless combined action be at once set on foot. For workmen we are afraid that the visit will be impossible, so high will be the prices for accommodation. From inquiries that we have made, the following seems most feasible, and may be carried into effect if time be not lost. Mr. Thomas Cook, the well-known excursion manager, has obtained reliable assurance for the accommodation of 1000 or more visitors at a time from April to the end of October, at the nearly uniform rate of 10s. a day, for bed, meat breakfast, dinner at *table d'hôte*, and lights, a small charge being added in some cases for service. By a regular succession of visitors in the full numbers, this reasonable scheme may be carried out. We recommend this plan to those who propose a visit to Paris, since we do not think that they will obtain such good terms by private contract—either singly or in parties.

Proposed Use of Soluble Glass.—We see that M. Velpeau has called the attention of scientific men to the anamo-inamovible bandages made by soluble glass, to replace the starch plaster of Paris and glue applications now used for bandaging fractures in England. The great advantage possessed by this glass is that it affords a firmer support, becoming quite hard in two or three hours, at the same time being readily removed by moisture. All these recommendations do not apply to the substances now in use, nor is their application as easy and neat as that of the soluble glass. It can be procured at a very moderate price from Mr. Rumney's Ardwick Chemical Works, Manchester, and we hope that as fair a trial will be given to it in England as has already been done on the Continent. The discovery of this glass was made by Fuch, in Munich; he prepared it by fuzing together sodic sulphate, and charcoal and sand; or either potassic or sodic carbonate with sand. It is of extensive use in the arts for stereo-chromic painting, and protecting substances of all kinds that might be damaged by moisture, &c., from atmospheric action.

Sterro-Metal Alloy Analysed by M. Sommaruza.—This alloy, from the manufactory of M. Rosthorn, exhibits a golden yellow colour, is readily forged like iron, and is easily worked by the file. It consists in 100 parts:

Of iron	4·66
,, copper	55·33
,, zinc	41·80
	101·79

The analysis was made at Vienna, in the laboratory of the Imperial Royal Establishment for Geology.

Visits to Chemical Works.—Dr. Williamson has done much service to the chemical students of his class at University College by taking advantage of the opportunities offered by the metropolis for obtaining practical information about chemical manufactures. During the last winter session excursions were made to such on Saturdays, when the pupils were little engaged, the Professor himself accompanying them, and showing the theoretical bearings of the processes carried on under their eyes. In this manner large gas and soap works, brass foundries, vinegar and oil of vitriol manufactories, among others, were visited, evidently to the satisfaction of all. The amount and kind of knowledge thus obtained can hardly be realised, and we would urge its adoption by all the chemical professors of the various metropolitan medical schools. In this way they will find that their pupils will acquire a much greater interest for the science, and their knowledge will be of a far more practical character. Such a mode of teaching certainly cannot be replaced by any series of diagrams and models, which are so often not looked at, or, if looked at, so soon forgotten. Of course it will be said that there is not time for the student to avail himself of this mode of working, even if he had the chance, from the necessary pressure of other work; but, in answer, it may be said that a few lectures could be dispensed with, and replaced by such excursions. Dr. Williamson has, by thus taking some extra trouble, earned the thanks of the students of his class, and we think that other teachers will soon feel equally thankful to him for showing how easily a new mode of instruction may be worked. There is no doubt whatever that the various manufacturers of London would invite any such friendly inspection with their usual courtesy.

On the Separation of Morphine and Strychnine,* by M. Rodgers.—M. Rodgers has observed that the reaction between strychnine and bichromate of potash may

* Equivalent to metallic iron, 22·311 per cent.; or cast iron, about 23·5 per cent.

* *Journ. de Chim. Méd.*

be masked by morphine. These two bases may be separated, either by chloroform, which dissolves the strychnine, or by benzol, which also dissolves the strychnine, but does not dissolve all the morphine.

Artificial Manure.—The manure applied at the Emperor's model farm, near Vincennes, by M. Ville, is prepared as follows :—

Slaked lime	200 kilos.	cost	2 fr.
Phosphate of lime . . .	400 ,,	,,	80 ,,
Nitrate of soda	500 ,,	,,	200 ,,
Potasse raffinée (carbonate of potash)	200 ,,	,,	190 ,,
	1300 kilos.		472 fr.

The above is the quantity required per hectare.

Recognition of Blood in Medico-legal Investigations.—The following written testimony of Dr. Duffield, of Detroit, in a murder trial in that city some months ago, was published in a late number of the *Detroit Tribune* :—

"Dear Sir,—In accordance with instructions received, I have examined the blood-stains upon the clothes and upon the boat seat sent up to Laboratory.

"The pieces I took from the lining of the right coat sleeve near the wrist afforded evidence of blood. Sections cut from the left leg of the pantaloons (one above the knee, one about at the knee, and one near the bottom of the leg) afford also evidence of blood.

"It was dried quite firmly on to the texture of the cloth, and must by its appearance have been at least six weeks or two months old. On cutting out the pieces from the pantaloons and sleeve, I moistened them with pure glycerine and allowed them to remain six hours. I then pressed out the liquid, drop by drop, as I required to use it, on the glass slip for the microscope, and subjected it to inspection. The blood corpuscles appeared shrivelled and smaller than in fish blood, but still preserved their rounded form and were able to be recognised as the organic features of blood.

"Blood corpuscles of an ox, cow, dog, or any of the mammalia, can be recognised from one another only by their size. On examining fresh blood of an ox and fresh human blood, the human blood will be found to contain the largest corpuscles, and can readily be recognised even on admixture with ox-blood corpuscles, which are smaller; but when time has elapsed, and the blood completely dead on the texture of the cloth, the corpuscles become shrunken, and give, as regards their size, very uncertain results. In the present case, all the corpuscles were round (in the blood taken from the clothes), and therefore belonged to one class—viz., the mammalia, *i. e.*, ox, dog, sheep, cat, &c. It could not belong to birds or fishes, as their corpuscles are oval.

"The spots on the seat were covered over with the eggs of a fish, which I scraped away and came down to dark spots, which had penetrated the wood. I took off the particles of wood with a clean sharp knife and rasped them into a powder, and soaked this powder with glycerine for ten hours. On putting a few drops of the glycerine under the microscope, I found abundant evidence of blood corpuscles, the round ones predominating. There were also oval ones, which could be either fish or bird blood.

"On the conclusion of this investigation I am compelled, though having experimented more or less for six years on the blood of animals, fowls and fishes, to depose that, when dried for any length of time and again moistened, great difficulty will be experienced in attempting to fix its origin by the size of its corpuscles.

"Alfred Russell, Esq." "SAMUEL P. DUFFIELD.

Action of Peroxide of Manganese on Salts of Copper,* by M. W. Schmid.—By shaking peroxide of manganese with a solution of sulphate of copper, a peroxide, CuO_2, is gradually produced, and the manganese dissolves. At the end of three weeks the exchange will be completed, and the filter will retain only a cupreous compound, nearly free from manganese. It is hardly necessary to say that the manganese employed must be perfectly pure. The exchange is made equivalent for equivalent. The peroxide of copper thus formed produces a strong effervescence when, after it has been moistened with a few drops of water, a little sulphuric acid is added. A similar peroxide has been obtained by Thénard by treating oxide of copper with oxygenated water. This is an antozonide, while peroxide of manganese is classed by M. Schönbein among the ozonides.

ANSWERS TO CORRESPONDENTS.

Vol. XIV. of the CHEMICAL NEWS, containing a copious Index, is now ready, price 11s. 6d., by post, 11s. 6d., handsomely bound in cloth, gold-lettered. The cases for binding may be obtained at our Office, price 1s. 6d. Subscribers may have their copies bound for 2s. 6d. if sent to our Office, or, if accompanied by a cloth case, for 1s. Vols. I., II., and VII. are out of print. All the others are kept in stock. Vol. XV. commenced January 4, and will be complete in 26 numbers.

*** In publishing letters from our Correspondents we do not thereby adopt the views of the writers. Our intention to give both sides of a question will frequently oblige us to publish opinions with which we do not agree.

Upas.—The first action of the poison of the Upas Antiar is to paralyse the heart. Sir Benjamin Brodie first made this out in 1812.

M. A. M. A. T.—By the ordinary process of cooking, roast meat is more nutritious than boiled, as by the latter operation the juices and salts partly diffuse into the water, whereas in roasting they are kept in the meat.

Medicus.—Chlorate of soda is more soluble than chlorate of potash, and has a pleasanter taste.

Academy of Sciences.—Up to the time of our going to press, the report of the proceedings of the Academy of Sciences on Monday last had not arrived.

W. A. F.—Your ammonia probably contains organic matter. This will account for its solvent action on sesquioxide of iron. Absolutely pure "volcanic" ammonia will not dissolve any trace of iron.

Combustion in Nitrogen.—Lecturer.—Both boron and titanium have been shown to be capable of burning in nitrogen gas with formation of nitrides. We are not aware whether either of these phenomena is sufficiently striking for lecture experiments.

Rusticus wishes for information on the following points :—1. Who was the real discoverer of coal-gas and its properties? 2. Where can I find the best history of illuminating substances generally from the earliest time, including the history of the various improvements in candles, lamps, night-lights, &c.? 3. Where can I find the best historical sketch of the development of photography from it scarliest date to the present time? 4. Where can I find any particulars of the life of Winsor?

Books Received.—The Dictionary of Photography, by T. Sutton, B.A., and G. Dawson, M.A.

TECHNICAL CHEMISTRY.

On a New Process of Organic Elementary Analysis for Substances containing Chlorine, by C. M. Warren.

(Continued from page 64.)

I. *Experiments with Oxide of Lead and with Oxide of Copper, placed in the anterior end of the combustion tube, as absorbents of Chlorine in the analysis of substances difficultly combustible.*

The substance selected for analysis, as a test of the process for that class of bodies which are difficultly combustible, containing but a small percentage of hydrogen, was commercial chloroform. The preparation employed was first subjected to redistillation.

Its boiling point was found to agree essentially with that assigned to pure chloroform in Gerhardt's *Traité de Chimie*. When the usual tests were applied, no impurity could be detected.

Experiment 1.—A mixture of oxide of lead and asbestos was placed in the anterior end of the combustion tube, between *c* and *d*, Fig. 2, as previously described. As chloride of lead was supposed to bear a pretty high temperature, without volatilisation or decomposition, the use of the air-bath was omitted in this experiment, and the oxide gently heated with a small flame from the combustion furnace. The combustion had not proceeded far, when it became apparent, from deposition of minute drops of liquid on the sides of the vacant part of the tube—from *b* to *c*, Fig. 2—that the combustion of the chloroform was incomplete, although no doubt could exist as to the presence of an excess of oxygen. This deposit of liquid, which, as already stated, was supposed to be a chloride of carbon, was found to be difficultly volatile, suffering partial decomposition, and leaving on the tube a brown deposit, which was not entirely removed by ignition in a stream of oxygen. The high temperature employed to burn off this deposit occasioned excessive heating of the posterior end of the mixture of lead oxide and asbestos; and this may have been the cause, to some extent, of the excess in the determinations of carbon and hydrogen, although subsequent analyses indicate that the sample of chloroform under examination contained a larger percentage of these elements—particularly of the latter—than belongs to pure chloroform. This experiment gave 11·47 per cent. of carbon, and 1·87 per cent. of hydrogen. Theory gives 10·07 per cent. of carbon, and 0·85 per cent. of hydrogen. The mixture of asbestos and oxide and chloride of lead was removed from the tube, and treated in the usual manner with a solution of bicarbonate of soda to obtain a soluble chloride. This operation was found extremely tedious. Even after treatment for more than two weeks, with occasional fresh portions of the bicarbonate and frequent agitation, the decomposition of the lead chloride was still found to be incomplete, and the operation was abandoned. As this is given in the text-books as a good process for the separation of chlorine from chloride of lead,* I am led to presume that in this case the excess of heat employed gave rise to the formation of an oxychloride, which is, doubtless, more slowly acted upon by the bicarbonate. This single experiment does not, therefore, prove that oxide of lead may not be employed in this process with good results, when used for easily combustible substances, and excessive heat is avoided. But it will, unquestionably, be found preferable to use a substance which will give directly a soluble chloride.

Experiment 2.—This experiment was conducted as the last, with only this difference—viz., that oxide of copper was substituted for the oxide of lead. No better results, however, were obtained. The reappearance of the difficultly volatile liquid in the vacant part of the tube, while there was assurance of there being no deficiency in the supply of oxygen, served to confirm the impression gained by the preceding experiment—that chloroform could not be completely burnt in oxygen alone, but that a substance having affinity for chlorine would have to be mixed with the asbestos, at the point where the combustion takes place.

II. *Experiments with Oxide of Zinc, mixed with the Asbestos in the posterior part of the Combustion Tube, as absorbent of Chlorine in the Analysis of Substances difficultly combustible.*

As already indicated, the chief object of this set of experiments was to determine whether the presence, at the point where combustion takes place, of an oxide capable of combining with the chlorine would have the effect to prevent the formation of the difficultly volatile liquid above mentioned, and thus remedy that defect in the process.

Experiment 1.—In this experiment three grammes of oxide of zinc were intimately mixed in a mortar with the quantity of asbestos necessary to fill the space between *a* and *b*, Fig. 2, and that part of the tube then packed with this mixture in the usual manner. A similar mixture, composed of asbestos and only one gramme of oxide of zinc, was placed between *c* and *d*. The space between *b* and *c* was still left vacant, in order to be able to observe the effect. On account of the volatility of the chloride of zinc, it was deemed advisable to retain the use of the air-bath to control the temperature of the anterior portion of the combustion tube, which, in this experiment, was not allowed to exceed 160° C. The result was, as anticipated, that no such condensation of liquid between *b* and *c* occurred. In order to gain from this experiment some idea of the degree of volatility of chloride of zinc under such circumstances, the two columns of asbestos were treated for chlorine separately. The solution obtained from the anterior column was found to contain but a trace of chlorine, giving only a milkiness with nitrate of silver; showing that the chloride of zinc does not travel far through a column of asbestos from the point where the flame plays directly on the tube.

Results of the Analysis.—0·2067 gramme of chloroform gave 0·0798 of carbonic acid, 0·0276 of water, and 0·7372 of chloride of silver.

		Calculated.		Found.
Carbon .	C_2	12	10·0671	10·5273
Hydrogen .	H	1	0·8473	1·4514
Chlorine .	Cl_3	106·2	89·0856	88·0455
			100·0000	100·0242

Experiment 2.—In this experiment the whole length of the combustion tube from *a* to *d* was packed with a mixture of asbestos and four grammes of oxide of zinc. The temperature of the anterior end of the combustion tube was regulated, as in the previous experiment, by means of the air-bath.

Results of the Analysis.—0·1339 gramme of chloroform gave 0·0506 of carbonic acid, 0·0156 of water, and 0·4768 of chloride of silver.

* H. Rose, *Chimie Analytique*, new French edition, p. 801.

		Calculated.		Found.
Carbon .	C_2	12	10·0671	10·3062
Hydrogen .	H	1	0·8473	1·2733
Chlorine .	Cl_3	106·2	89·0856	87·9014
			100·0000	99·4809

These two analyses, agreeing as they do so closely, indicate that the chloroform analysed contained larger percentages of carbon and hydrogen—especially of the latter—and a correspondingly smaller percentage of chlorine than the theoretical quantities, occasioned probably by the presence of some impurity. This view is supported by calculations made on the assumption that the excess might have arisen from volatilisation of chloride of zinc, or from incomplete absorption of the chlorine, which would make the chloroform contain from 2 to 6 per cent. more than the theoretical quantity of chlorine. These results are regarded, therefore, as satisfactorily establishing the utility of this process in the analysis of chloroform. But the analysis of this body, containing as it does 89 per cent. of chlorine and only $\frac{80}{100}$ths of 1 per cent. of hydrogen, must be considered as an extreme case, and does not prove the process a good one for other classes of substances.

The next step, therefore, was to determine whether the process would be equally efficient in the analysis of substances rich in hydrogen, the combustion of which would give rise to the formation of a large quantity of hydrochloric acid. The substance selected for analysis, to settle this question, was chloride of amyl.

(To be continued.)

PHARMACY, TOXICOLOGY, &c.

On the Examination of Diabetic Urine; New Reagent for Glucose, by L. B. Francqui *and* L. Vande Vyvere.

After noticing the several reagents used, and pointing out their special inconveniences, the authors propose a solution containing oxide of bismuth as being free from these defects. "We have found," they say, "that hydrate of bismuth dissolves in caustic potash, under the influence of certain organic bodies, such as glucose, cane-sugar, dextrine, tartaric acid, &c." These solutions do not form a precipitate on boiling, except in the case of glucose.

Guided by these results, we are induced to recommend, for the detection of glucose in urine, the following process, which cannot give rise to any fallacy:—

Prepare the reagent by precipitating a solution of acid nitrate of bismuth by a great excess of caustic potash, and pour a solution, drop by drop, into the moderately heated solution until the precipitated hydrate of bismuth is completely redissolved.

To recognise a diabetic urine, heat a portion with the above solution.

After a few minutes' ebullition, the urine becomes brown, and metallic bismuth is then precipitated in the form of a black powder of crystalline appearance, adherent to the glass, if glucose is present.

We have satisfied ourselves that the principles contained in normal urine, such as urea and uric acid, do not precipitate the above reagent. Albumen only causes a brown colour and a slight turbidity, which we consider to be due to the formation of sulphide of bismuth.

Sulphuretted urines also give a black precipitate in a solution of oxide of bismuth in potash and tartaric acid; but this reaction cannot be confounded with that caused by glucose.

It is, besides, easy to recognise and (if desired) to separate the albumen. Thus, on bringing to ebullition the urine of a person suffering from Bright's disease, the liquid becomes turbid, opalescent, and deposits coagulated albumen.

As to sulphides and sulphuretted hydrogen, these are easily recognised by means of hydrate of lead, which these compounds darken.—*Gazette Médicale.*

PHYSICAL SCIENCE.

*On the Ventilation of Icebound Fish-ponds,** *by* Charles Tomlinson, *F.C.S.*

It is, I believe, a common practice when a fish-pond freezes over to break the ice in order that the fishes may obtain a proper supply of air, and it is supposed that if this precaution be neglected the fishes will perish. If this be so, the question arises—How is the icebound water of lakes and ponds far removed from the dwellings of man, where the fishes are not preserved, supplied with air?

On consulting books for an answer to this question, I was surprised to find some contradiction on the part of naturalists of repute. Thus Swainson,† after lamenting the loss of between thirty and forty fine tench, the dead bodies of which were found floating on the surface of his pond on the breaking up of the long and severe frost of 1837-8, says—"The people about the place assert that this mortality would not have happened had holes been broke in the ice for the admission of air; but were this absolutely necessary in all cases, it would follow that the tench of all such ponds as had not been opened would have been likewise killed." Mr. Swainson's own opinion was, that the tench had been killed by cold.

In opposition to this opinion, we must refer to the extraordinary vitality of certain fishes, &c., under the influence of a much lower temperature than we get in this climate. Franklin,‡ during his residence in the Arctic regions, noticed that "the fish froze as they were taken out of the nets, and in a short time became a solid mass of ice. . . If in this completely frozen state they were thawed before the fire, they recovered their animation. This was particularly the case with the carp, and we had occasion to observe it repeatedly, as Dr. Richardson occupied himself in examining the structure of the different species of fish, and was always in the winter under the necessity of thawing them before he could cut them. We have seen a carp recover so far as to leap about with much vigour after it had been frozen for thirty-six hours." Hearne, Ellis, and others state that mosquitoes and other insects frozen into a black solid mass, spiders frozen so hard as to bound from the floor like a pea, frozen leeches, frogs, and snails, all recovered their energies when thawed before the fire. Mr. Jesse also relates the case of a golden carp recovering after having been completely frozen in its vase of water.

These facts seem to prove that although fishes may be made torpid by cold, and so not require air, yet in their active state they must be supplied with this necessary condition of life. The appetite for air is, no doubt, different in different species. If carp and tench in an aquarium

* Communicated by the author.

† "Natural History of Fishes, &c.," in the "Cabinet Cyclopædia," vol. i. p. 50.

‡ "Journey to the Shores of the Polar Sea, 1819-22," p. 248.

be watched, it will be found that the carp frequently seek the surface for air, while the tench remain at the bottom. If various species be crowded together in a tub of water, such as minnows, dace, roach, gudgeons, &c., some will die long before the others for want of air. I remember seeing one morning, in the market-place of Cologne, tubs of water crowded with carp. They did not attempt to move about, but remained with their mouths just out of the water, imbibing the air. I was told that it is the practice to return to the stews until the next market-day the fish that had not been sold. I have also read of carp being kept alive all the winter, hung up in nets in cellars with wet moss about the gills, the moss being occasionally sprinkled with water.

Boccius,§ a practical manager and constructor of fish-ponds, distinctly recognises the necessity of supplying air to the water during frost. He directs that a hole, about two feet in diameter, be opened in the ice, and that a faggot of sticks, or of brushwood, be inserted in the hole to keep it open and shelter it from the wind. Mr. Swainson's pond already referred to was "fringed with many aquatic plants," and the only use assigned to them is "abundant shelter thus afforded to the fish," whereas one purpose served by such plants is to keep the water longer in a liquid state.

But perhaps it may be said that in stews and preserves the fishes are much more crowded than they are likely to be in a state of nature, and hence the necessity for making holes in the ice. The crowded state of the aquarium prevents the proper ventilation of the water, and this I believe to be the main cause of the failure of that interesting institution. I know of several curious cases of failure, all referable to want of air. One kept in a house in a crowded thoroughfare failed, as I think, from the constant vibration loosening the adhesion of the air to the water. The fishes were always at the surface gasping for air, and repeated syringing of the water did not remedy the mischief.

Referring to the experiments reported in last week's Chemical News on the freezing of aerated waters, it appears that when such waters are frozen rapidly, the air becomes entangled, and opaque, milk-white ice is the result; but where the cold operates gradually, clear crystalline ice, from which air is excluded, is formed; or, if the air cannot escape, clear ice is first formed, and afterwards the opaque aerated ice. Similar effects are produced in nature. In a shallow pond a sudden frost will produce much of this opaque ice; the inhabitants will be deprived of air, and thus be suffocated. A few years ago a friend wrote to inform me that a considerable number of the small blue roach had been killed in the ponds (or pits, as they are locally called) about Bromborough, near Birkenhead, from the sudden freezing over of the surface. These pits are shallow, and a sudden frost would entangle much of the air of the water in the ice. On the other hand, if the cold increase gradually, the water has time to separate the air, and no sooner is a thin crust of ice formed on the surface than this separation proceeds downwards, and often with such effect as to collect the air in lenticular masses, which appear of a light colour amidst the black ice. In this way the freezing proceeds downwards, and if the water be moderately deep, the fishes not only enjoy a comparatively mild temperature, but have air enough until the frost breaks up, unless, indeed, it be of unusual duration.

Deep ponds and lakes are slow in freezing, because the whole body of water is slow in attaining its maximum density by cold, and until this is done the surface cannot sink to 32°. On the other hand, rivers and streams are slower in freezing than stagnant shallow water, the motion interfering with convection and also with crystallisation. Ponds and lakes are often fed by springs and streams, so that if the former be frozen on the surface the latter may be active, and, if they find their way into the icebound water, will carry in much air.

Mr. Kohl‖ refers incidentally to the powerful currents under the ice of Lake Superior. He is describing the method adopted by the natives for spearing sturgeon. A fisherman cuts a hole in the ice about two feet in diameter, builds over it a hut of bush work, and covers it with a cloth. This serves for sheltering and concealing his body. The light passes through the transparent ice, and illuminates the waters to a great distance around. These waters are so transparent that he can see to a distance of forty or fifty feet. The spear is from thirty-five to forty feet in length, and is attached to a line. Armed with this, and aided by an assistant, he watches the currents that occur in many parts, and in which the finest sturgeon are found. The fishes generally move up the stream at various rates of speed, either quickly or slowly, or they stop altogether, until, being within reach of the spearsman, one is struck and secured. Other fishes are enticed nearer the surface by means of artificial decoy fish of wood or bone.

In smaller collections of water, where the temperature is low enough to lock up the springs, air may be supplied by a portion of the water sinking into the soil. There is a phenomenon common in country lanes when a sharp frost sets in immediately after rain. The water that collects in the wheel-ruts and in the hoof-prints of horses, &c., freezes at the surface in blades of ice that cross at angles of 60°. If this ice be tapped with a stick a few hours after it has been formed, it will be found not to cover water, but a hollow space from which the water has been absorbed by the soil. This kind of ice is called "cat's ice" by country people, probably from its treacherous nature.

If a portion of the water of a pond or lake be thus absorbed by the soil, the ice is left unsupported, except at the edges, and air would find its way in either through cracks in the ice or through the soil. A moderately porous soil would let in air. Indeed, it has been proved by the experiments of Messrs. Pettenkofer and Roscoe that a brick wall by its porosity is an important aid to ventilation, "an actual and very large diffusive interchange going on within the pores of the brick and mortar."

If what I have said is not enough to show how icebound fish-ponds are ventilated, I shall be glad if some of the readers of the Chemical News will throw a little further light on the subject.

Highgate, January 31.

The Abbe Moigno, on Monday evening, was invited by H. M. the Emperor to give an evening lecture at the Tuileries, on electricity, before the Court. All the modern appliances of the fluid were treated upon by the learned lecturer, whose profound knowledge is combined with a charming ease and grace of diction. Several times he was complimented by the Empress on the success of his experiments.

FOREIGN SCIENCE.

(From our own Correspondent.)

Paris, February 11, 1867.

Last year a very forcible powder was proposed, consisting of chlorate of potash and tannic acid, but which was far too detonating. Dr. Borlinetto, Professor of Chemistry at the University of Padua, had the idea at first to substitute gallic acid; the powder became less violent, but it was still too detonating. From gallic acid he passed to picric acid, very rich in carbon; a mixture of two equal portions, well pounded together, of chlorate of potash and picric acid forms a powder which detonates, emitting a very bright white flame, but which is still too dangerous, as a slight pressure is sufficient to cause it to explode. It was absolutely necessary to abandon the use of chlorate of potash. M. Borlinetto substituted for it the nitrate of potash; and the following mixture—

Nitrate of potash	. .	10 parts
Picric acid	. . .	10 ,,
Bichromate of potash	.	8·5 ,,

gave an excellent powder, that can be compared with the best sporting gunpowder. These three substances should be intimately mixed. There is no danger of this powder exploding by friction or percussion; it leaves scarcely any residue after combustion. The bichromate of potash is absolutely necessary in order to give it expansive force. The nitrate of potash is decomposed at a red heat into oxygen and nitrite of potash; at this same temperature a portion of the oxygen of the bichromate of potash unites with the carbon of the picric acid, giving rise to a white heat, which completes the decomposition of the nitrate of potash.

Paper lightning-protectors for telegraphic lines are now attracting attention They consist of two well-smoothed brass plates from 25 to 30 square centimetres (3·87 to 4·65 square inches) placed one above the other, and separated by a sheet of paper; one of the metal plates is in connexion with the line, the other communicates with the earth. As soon as a rather strong tension occurs on the line, sparks pass from one plate to the other, perforating the paper, and the electricity passes into the earth very easily. M. Guillemin proposes to replace the paper by a very thin layer of mica. The mica is a better insulator; it does not absorb damp; it cannot produce carbon, since it is of a mineral character; moreover, its ready cleavage allows of its being split into plates thinner than a sheet of paper. The administration of the telegraphic lines purpose placing very shortly a great number of these lightning protectors in places subject to be attacked most frequently by the electric fluid of the atmosphere. Practical trial is the only method by which the modification proposed by M. Guillemin can be appreciated. We hope the results will be favourable.

When Nichol's prisms are used as polarisers or analysers in delicate optical measurements, a very strange anomaly may be at once remarked: the azimuths of extinction do not occur at a distance of 180°. The error can amount to several tens of minutes. This error would be fatal to the use of the Nichol's prism, if we could not discover the cause, diminish, and remedy it. M. Cornu first pointed out this cause, and he has given the following explanation. The axis of rotation of the prism, or rather that of the instrument which carries it, does not coincide with the plane of the principal section; hence the ray which traverses takes different directions in the prism according to the azimuth, and the polarisation that it is subject to is not parallel to the plane of the optical symmetry of the crystal. When the lines of entry and quitting the prism are quite parallel, it can be regulated by trial; in general the error will be only attenuated and not annulled. It is eliminated in proceeding by crossed observations. In fact, it is easy to demonstrate, by a very simple calculation, and by direct observation, that the error e of the normal azimuth is given by the formula

$$e = A(z + a);$$

A and a being the constants; z, the observed azimuth. We easily deduce that the mean of the reading of the azimuths, which should strictly differ by 180°, gives, after the subtraction of 90°, the real azimuth. The error is eliminated of its own accord, if we choose for the measurements of the azimuths the mean of two positions of extinction, whether for the analyser or for the polariser.

The scientific world has made during these last weeks a truly extraordinary discovery, which has made known the real nature of the swarm of shooting stars which are seen in the nights of August 10 to 11, and of November 13 to 14. M. Schiaparelli, Director of the Brera Observatory at Milan, was the first to give the character of a true theory to the opinion put forth by Kepler, and which attributed a stellar origin to shooting stars. The showers of August and November were formerly spherical nebular masses, arriving from the regions whence come the comets, and which, under the influence, at the same time attractive and perturbative, of some great planet, became considerably elongated at the same time that they began to describe a very oval elliptical orbit, which brought them periodically within the sphere of attraction of the earth and under the oxidising and igniting influence of the terrestrial atmosphere. In the meteorological bulletin of the observatory of the College of Rome for December 31, 1866, M. Schiaparelli gave the following elliptic elements of the orbit of the shower of August 10 :—

Perihelion passage . . .	10·75 d. August.
Longitude of perihelion . .	343°28′
Longitude of ascending node . .	138°16′
Inclination of orbit . . .	64°3′
Perihelion distance . . .	0·9643

Motion retrograde.

M. Schiaparelli was also the first to make known the almost perfect identity of these elements with those of the great comet of 1862, such as they result from the last calculations of Dr. Oppolzer :—

Perihelion passage . .	22·9 d. August, 1862.
Longitude of perihelion .	344°41′
Longitude of ascending node .	137°27′
Inclination of orbit . .	66°25′
Perihelion distance . .	0·9626

Motion retrograde.

It is impossible to think that this coincidence can occur by chance. The comet of 1862 essentially forms part of the shower of falling stars. In this same letter, of December 31, M. Schiaparelli gave the elements of the very elongated orbit of the shower of falling stars of November 13. Up to that period M. Le Verrier had announced nothing. It was only on the first days of January that he announced that, at the meeting of the Scientific Society of France on January 14, he would treat upon the origin of shooting stars. In fact, he made a communication upon this subject soon after, followed (January 21, 1867) by a lecture at the Academy of Sciences, in which, without the slightest mention of M. Schiaparelli, he reproduced his theory: this swarm of asteroids has come to us from the depths of space, and in the interval of each of these returns it returns towards the superior planets. A body coming from a distance, animated with a great velocity, at the moment when it attains the minimum distance of the earth from the sun, could not be fixed by the feeble action of the inferior planets, in an orbit of one or two years. We are convinced of this by calculation, and we find a physical proof of it in the fact that the shower of falling stars which repasses the earth every thirty-three years is not completely deranged in the *ensemble* of its orbit; otherwise it would not be seen at regular intervals. Admitting, then, that the shower circulates in an orbit of 33¼ years, that the perihelion distance is equal to 0·989

of the radius of the terrestrial orbit, at the mean of the apparitions we have for the first elements of the orbit :—

	Years.
Duration of the revolution . .	33·25
Semiaxis major	10·34017
Eccentricity	0·904354
Perihelion distance	0·989000
Inclination of orbit	14°41′
Longitude of ascending node .	51°18′
Longitude of perihelion . . .	42°24′

These elements differ so little from those of M. Schiaparelli, that all the glory of the discovery can be attributed to him. The following is all, in reality, that M. Le Verrier added to it (*Comptes Rendus* of the Academy of Sciences, vol. lxiv. p. 97) :—

"The mass of shooting stars could not have been introduced and thrown into its actual orbit, except by some energetic disturbance. . . . We cannot be otherwise than struck with the circumstance that the shower of November extends as far as the orbit of Uranus, and a little beyond it; the more so as these orbits cross each other, nearly at a point situated, after the passage of the swarm, at its aphelion and above the plane of the ecliptic. We are then bound to inquire whether Uranus and the cluster of asteroids could not have been situated simultaneously at this point—that is to say, in the neighbourhood of the node of the orbit. . . . To resume, all the phenomena observed can be explained by the presence of a globular cluster cast against Uranus in the year 126 of our era, in the orbit which observations assign to the mass of asteroids of November. . . . The action of Uranus must have unequally changed the absolute velocities of the corpuscles, and this action surpassing the attraction resulting from their total mass, the cluster became disengaged and extended over the whole periphery of the ellipse, &c." Thus, the problematic interference of Uranus in the year 126 of our era is all that belongs to M. Le Verrier in this question. We say *problematic*, because the passages quoted by M. Schiaparelli from the ancient Indian poems seem to show that the shower of shooting stars of November 13 had been observed long before the year 126 of our era.

M. Le Verrier did not confine himself to the communication of the Scientific Association of France, at the Academic Lecture of January 21; he gave to his conjectures the solemnity of a letter, addressed to his illustrious colabourer in the field, Sir John Herschel, inserted in the *Moniteur*, and in which, faithful to his antecedents, he was silent as to the name of M. Schiaparelli, and attributed all the merit to himself of an explanation which only belongs to him by virtue of a very secondary hypothesis. We are very sorry to be obliged to acquaint our readers that the tactics of M. Le Verrier have been crowned with the most complete success, and that the venerable patriarch of Collingwood has fallen into the mistake. In the answer, also inserted in the *Moniteur*, M. Schiaparelli does not even appear in the background, and all the praise is given to M. Le Verrier. We ask all our brother members of the press to unite with us in condemning a really unjust spoliation. M. Le Verrier has trampled under foot all the laws of scientific probity, in not taking into any account whatever the publications made by M. Schiaparelli in the meteorological bulletin of the Roman College, and especially of the second, reproduced entirely in *Les Mondes* of January 26, and which is a complete mathematical theory of the observed phenomena.

Since the communication of M. Le Verrier, M. Schiaparelli at Milan, and M. Paten at Altona have called our attention to the truly extraordinary identity of the elements of the shower of stars in November with those of the comet of M. Tempel (first comet of 1866), also recently mentioned by M. Oppolzer.

	Years.
Duration of the revolution .	33·18
Semiaxis major . . .	10·32479
Eccentricity . . .	0·905420
Perihelion distance . .	0·97652
Inclination	17°18′
Long. of ascending node .	51°25′

Motion retrograde.

We do not know that a more unlooked-for and extraordinary fact in the history of astronomy can be cited than that of the identification of the orbits of these two showers of shooting stars of August and November with the orbits of two comets which have recently appeared, as demonstrating the most astonishing of approximations. Let us repeat again that the glory of this brilliant discovery belongs wholly and entirely to M. Schiaparelli, and that M. Le Verrier can only claim the merit of a conjectional perception of it. F. MOIGNO.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, February 7.

Professor W. A. MILLER, *M.D., V.P.R.S., President, in the Chair.*

THE proceedings were opened in the usual manner, and the following gentlemen were balloted for, and duly elected Fellows of the Society, viz. :—James William Hudson, Ph.D., F.S.A., Principal of Trafford College, Manchester; Mr. Joseph Ince, Associate of King's College, London, and Member of Council of the Pharmaceutical Society, 26, St. George's Place, Hyde Park Corner; Mr. George Ottley, 196, Walworth Road. The candidates whose names were read for the first time were—Major R. C. Stewart, Deputy-Assistant Adjutant-General to the Forces, Horse Guards, and 12, Prince of Wales's Terrace, Kensington Palace; Mr. William Price Bonner, 69, Mark Lane; Mr. James Campbell Brown, 65, Bon Accord Street, Aberdeen; and Mr. J. Hersee Freeman, Stratford House. For the second time were read the names of Mr. Jonathan Hearder, Plymouth; Mr. Henry Watson Eve, M.A., Wellington College, Wokingham; Mr. William Thurston Waite, 37, Jewry Street; Mr. Martin Henry Payne, 47, Mortimer Street, Cavendish Square; Mr. Frederick George, of Cheltenham; Mr. R. R. H. Davey, War Office, Pall Mall.

A "*Note on some Varieties of Orchella Weed and Products obtained therefrom*," by JOHN STENHOUSE, LL.D., F.R.S., was read by the Secretary. The author commences by referring to a previously described gigantic variety of *Rocella tinctoria*, known as "Valparaiso weed,"* and to the fact of Gerhardt having suggested (with truth) the identity of the orsellic acid prepared from it and the lecanoric acid of Schunck. The preparation of orcin and erythrite are then treated of, and for this purpose the weed is exhausted with lime-water, or milk of lime, when, upon addition of hydrochloric acid, erythrin is precipated. This intermediate product is then boiled with fresh milk of lime in an apparatus provided with a long condensing tube so as to guard against the action of air, submitted to carbonic acid or sulphuric acid to remove the lime, and evaporated cautiously to dryness. The orcin is then extracted from the mixture by repeated treatment with warm benzol, and the residue is boiled with water, filtered when cold, and evaporated, in order to furnish the erythrite. When purified, the orcin forms colourless crystals, soluble in water, which were found to yield an amorphous yellow product by the action of chloride of sulphur. *Orsellinic ether* was obtained by boiling the pasty erythrin with alcohol, and afterwards purified by dissolving in hot benzol. From this body the *di-iodorsellinate of ethyl* was procured by the action of a dilute solution of chloride of iodine. It was crystallised from bisulphide of carbon, and, finally, from spirit in small needles,

* *Phil. Trans.*, 1848, page 63.

which are very slightly soluble in water. A combustion of this substance was made. The analytical results established the formula, $C_8H_5I_2(C_2H_5)O_4$. Dr. Stenhouse describes the corresponding methyl-compounds, and also refers to a modification of his method of determining the amount of colour-yielding principles in lichens by the employment of a standard solution of hypochlorite of sodium.

A paper "*On the Eggs of Corixa mercenaria*," by Dr. T. L. Phipson, was read by the Secretary. These eggs were said to be abundantly deposited by the insect (a kind of boat-fly) upon reeds growing on the banks of certain fresh-water lakes in Mexico, and were collected, dried in the sun, ground into a kind of flour, and used by the natives as a nutritious food. The structural character of the eggs is illustrated in the author's paper by a sketch. They appear to be smaller than a pin's head; and by microscopical examination it was ascertained that the *larvæ* had escaped, leaving only the rigid envelope, submitted to analysis, and found to contain 6·2 per cent. of nitrogen. The eggs of the *corixa* are said to be composed almost entirely of chitine, with only 5 per cent. of mineral matter (chiefly phosphate and carbonate of lime). The author disputes the view advanced by Fremy, to the effect that chitine is a kind of cellulose, at the same time stating his belief that it is a glucoside, $C_{18}H_{15}NO_4$, yielding glucose and lactamide (or some such body) by the action of mineral acids. M. Virlet d'Aoust describes the occurrence of these eggs as contributing towards the formation of a new oolitic limestone rock at the bottom of the Mexican lakes.

The President moved a vote of thanks to the authors respectively, and invited Dr. Matthiessen to deliver a lecture "*On Alloys*."

Dr. Matthiessen commenced by defining an alloy to be "a solidified solution of one metal in another." The metals might be conveniently divided into two classes, according to whether or not certain physical properties of the constituents reappeared in the compound. The metals in the first class (A) were lead, tin, zinc, and cadmium; in the second class (B), all the rest. If either of these four metals were alloyed amongst themselves, the metallic mixture always presented physical characters, which were the mean, by weight or volume, of the component metals. Zinc and lead would not unite to form alloys, or only in minute proportion could one metal be dissolved in the other; thus lead was saturated by 1·6 per cent. of zinc, and, conversely, zinc by about 1·2 per cent. of lead. If equal weights of the two metals were melted together and allowed to cool very slowly in a cylindrical mould surrounded by hot sand, the separation was almost complete, the heavier lead subsiding to the bottom. The case of zinc and bismuth was somewhat similar; only 2½ per cent. of zinc could be dissolved in bismuth, whilst a variable quantity, from 8 to 14 per cent., of bismuth was taken up by zinc. Alloys did not, in the lecturer's opinion, come within the definition of true chemical compounds, but were intimate mixtures, perfectly homogeneous throughout, like ordinary glass. There might be a few exceptional cases, such as the sodium amalgam, in the production of which heat was given out, so also with platinum, or gold and tin; but the addition of lead to melted tin had a cooling effect, and copper dissolved but very slowly in the latter metal, although the copper-tin alloy had new and remarkable properties. Dr. Matthiessen then proceeded to illustrate by experiment the fact of the specific heat of the copper-tin alloy being the mean of the specific heats of the metals composing it. For this purpose two short cylinders were taken; one was the copper-tin alloy (gun-metal), and the other a compound bar of the same weight, made up of a cylinder of copper joined to one-tenth of tin. These were suspended by string in boiling water, and heated together for a few minutes, then withdrawn and cooled in two identical cups of cold water. By a differential thermometer, in the shape of the letter M, the rise in temperature of the water was shown to be in both cases exactly equal. A similar experiment, made with lead and zinc of equal weights, at once indicated the fact of the specific heat being greater in the case of zinc. The rate of expansion by heat was shown by a modification of Daniell's pyrometer, the gun-metal and compound copper and tin bars being surrounded by a glass tube charged with steam. In both instances the needle was deflected to the same extent. The lecturer then referred to the crystalline form and fusing points of alloys; these were characters upon which the chemical view had usually been based, but a lower fusion temperature was common to all mixtures. Thus the alloy of potassium and sodium was permanently liquid like mercury, a mixture of their chlorine compounds, or, indeed, of any two metallic chlorides fused lower than the mean temperature; so also did the mixed fluxes employed in metallurgical operations. Mr. Cooke has stated that alloys of antimony and zinc, containing from 43 to 64 per cent. of the latter, crystallise in a different form from all the rest. The same had been said of the gold-tin alloy containing from 27 to 43 per cent. of gold. With regard to the copper-zinc alloys, the lecturer said that they all crystallised in the same form, and that therefore definite forms could be obtained when the constituents were not in atomic proportions. The properties of heat and electric conduction were next treated of; these were said by MM. Wiedemann and Franz to be alike. A comparative experiment was then shown, which indicated how rapidly the conducting power of copper for heat was destroyed by the introduction of a metal of Class A, such as tin, whilst the lead-tin alloy presented the mean result of the component metals. The results were as follows:—

	Heat-conducting power.
Copper	100
Copper-tin alloy	8
Tin	12
Lead-tin alloy	11
Lead	8

Several very interesting observations were brought forward by Dr. Matthiessen in connexion with electric conductivity of alloys. The metals of Class A are all bad conductors, and when alloyed with each other they conduct electricity in the ratios of their relative volumes. (Indicated by straight lines in the diagram.) Metals of Class B, such as gold and silver, do not, when alloyed with each other, conduct in the ratios of their relative volumes, but always in a degree inferior to the calculated mean. (Shown in the diagram by a rapid decrement on *both* sides of the curve.) The alloys of metals in Class A with one of those in Class B (for example, the copper-tin alloy) are like the last, but they show a very rapid decrement on the side of the metal belonging to Class B (to the extent of 85 per cent. copper in the instance quoted), then running in an almost straight line to the other side, representing the metal (tin) of Class A. In other words, there is very little difference between the conducting power of gun-metal and of pure tin, although copper itself is eight times better than tin. The sonorous qualities of metals and alloys were next taken into consideration. Bars of copper, tin, and a tin-copper alloy, when struck, all emitted a dead sound, but gun-metal gave a clear ringing tone. Brass rings well, but zinc is dull. Steel is infinitely superior in sonorous quality to malleable iron. Elasticity was then exemplified by hanging weights to a series of metallic wires twisted in a spiral form. Copper was straightened by a weight of 500 grammes, and tin by 50 grammes; but the copper-tin alloy supported the 500 without loss of figure. The difference between pure gold wire and gold with copper was very marked; so also the silver-platinum alloy proved greatly superior in elasticity to either of the individual metals. Spirals of hard-drawn malleable iron and steel showed, of course, the extremes, with least variation in chemical composition. Tenacity was shown by the help of a draw-

bench with spring balance attached. The experiments had to be rapidly performed, and the results were only true, therefore, between somewhat wide limits. The breaking weights of wires of equal diameter, 23 wire gauge (Birmingham), were nearly as follows:—

Copper wire, hard drawn .	about 30 lbs.
Tin	under 7
Copper-tin alloy (hard-drawn)	. 80 or 90
Tin-copper alloy . . .	about 7
Lead	under 7
Lead-tin alloy . . .	about 7
Gold (hard-drawn)	. 25 or 30
Gold-copper alloy ,, .	. . 80
Silver ,, .	about 50
Platinum ,, .	. ,, 50
Silver-platinum ,, .	. ,, 80
Iron ,,	. about 80 or 90
Steel ,,	upwards of 200

The lecturer proceeded to show how completely the scientific deductions coincided with the results of practical experience; thus the "turning-points" indicative of marked physical properties were found to mark the proportion of metals entering into the composition of a variety of useful alloys. Thus, in

Brass, 28 per cent. of zinc.
Gun-metal, 12 per cent. of tin (approximately).
Gold of 22 carat standard (with copper).
Dental alloy of silver and platinum.

The last-named alloy had been chosen as the standard for electrical resistance by the British Association Committee. The sound and electrical curves differ only by 5 per cent. in the case of the copper-tin alloy, and other physical characters are marked in gun-metal; but the lecturer hesitates to accept the expression $Cu_{14}Sn$, which would be demanded on the assumption of its being a chemical compound. Whilst the metals of Class A produce alloys having normal physical properties, those of Class B are so entirely changed by admixture of small quantities of other metals that the resulting alloys can only be viewed as "solidified solutions of allotropic modifications of the metals in each other." Dr. Matthiessen concluded by referring to the discovery of a new factor, which, if multiplied by the number representing the conducting power of a metal alloyed with it, expresses the electric value of such metal in the alloy. The process is illustrated in the following diagram:—

Conducting Power, in terms of British Association Unit, Metre Length, Millimetre Diameter.

Metals.

Copper	47·50
Zinc	13·80
Tin	5·88
Lead	3·96
Bismuth	0·60

Alloys containing

Copper tin . .	4·190	·851 Cu	·149 Sn
Copper zinc . .	10·330	·706 Cu	·294 Zn
Bismuth tin . .	0·117	·991 Bi	·009 Sn
Bismuth lead . .	0·122	·982 Bi	·018 Pb

Values obtained for Conducting Power of

Copper from 1st alloy . . .	3·89
,, ,, 2nd ,, . . .	8·89
Bismuth ,, 3rd ,, . . .	0·0677
,, ,, 4th ,, . . .	0·052

$$\begin{array}{c} \cdot 149 \times 5 \cdot 88 = 0 \cdot 88 \\ 4 \cdot 19 - 0 \cdot 88 = 3 \cdot 31 \\ \frac{3 \cdot 31}{\cdot 851} = 3 \cdot 89 \end{array}$$

$$\frac{3 \cdot 89}{5 \cdot 88} = 0 \cdot 662 \qquad \frac{0 \cdot 0677}{5 \cdot 88} = 0 \cdot 0115$$

$$\frac{8 \cdot 89}{13 \cdot 8} = 0 \cdot 664 \qquad \frac{0 \cdot 052}{3 \cdot 96} = 0 \cdot 0130$$

Conducting Power of

Copper = 0·650 × conducting power of metal alloying it.
Bismuth = 0·012 × ,, ,, ,, ,,

Professor Graham referred to the circumstance of the metals in Class A being those which are attacked or diffused into mercury by virtue of an action similar to that of salt into water. He thought, therefore, that Dr. Matthiessen's view regarding the constitution of alloys was borne out by reference to analogous cases of union.

Dr. Odling remarked upon the difficulty of stating exactly the conditions upon which a chemical compound might be formed. There were so many degrees of affinity exerted between different elements that it was necessary to define the term "chemical compound" before it was possible to say whether or not the class of actions involved in the formation of alloys was comprehended. He would not say that the metals united with the affinities of oxygen for hydrogen, but he considered that the force in question was comparable with that occurring during the solution of salt in water.

Dr. Matthiessen quoted, in reply, the case of sulphur and copper, which produced a definite compound, from which any excess of the first-named element could be driven off by heat. In the case of alloys, it was found impossible, as a rule, to produce combinations of definite character. Thus, in the case of the gold-tin alloys, he had obtained five crops of crystals of definite form, but not of constant chemical composition.

The President moved a vote of thanks, carried by acclamation, and adjourned the meeting until the 21st inst.

PHARMACEUTICAL SOCIETY.

February 5, 1867.

T. H. Hills, *Esq., Vice-President, in the Chair.*

The first paper read was one "*On the Preparation of Spirit of Nitrous Ether*," by Professor Redwood. The author commenced his paper by alluding to the various published processes for the preparation of spirit of nitrous ether, referring more especially to the process of the London Pharmacopœia of 1851. He mentioned that, although spirit of nitrous ether had been much used as a medicine for many years, there had hitherto been no satisfactory mode of preparing it, the strength varying from one to twelve per cent. When the British Pharmacopœia of 1864 was issued, it was hoped that a process would be given which would enable manufacturers to produce spirit of nitrous ether of a uniform strength, but such was not the case; for, although on reading the process it appeared to be an improvement, it was found to be impossible to produce the nitrate of soda of a uniform composition. Professor Redwood then proceeded to explain the process of the forthcoming new edition of the British Pharmacopœia, which consists in mixing 2 oz. of sulphuric acid and 2½ oz. of nitric acid with 1 pint of rectified spirit, pouring the mixture into a retort containing 2 oz. of fine copper wire, and supplied with a thermometer, allowing 15 oz. to distil over, and then adding 40 oz. of rectified spirit. This process appears to be very simple, and even more economical than former Pharmacopœia processes, so that it is likely to be successfully followed by wholesale manufacturers. The advantage is, that with a small quantity of nitric acid a mixture is obtained which will yield nitrous ether in a constant quantity and of a certain strength, sulphate of copper remaining in the retort. Professor Redwood explained that the process did not yield a pure spirit. He hoped to pay more attention to this at a future time; but it would have been unadvisable to have introduced into the Pharmacopœia a pure spirit of nitrous ether, when it was not known whether spirit of nitrous ether owed its medicinal qualities to the nitrous ether or to the aldehyd it contained.

Mr. Watts then read a paper on "*A Critical Examination of the various Published Processes for the Estimation of Tannin.*"

ACADEMY OF SCIENCES.

February 11, 1867.

"*On the Isomeric States of Silicic Acid, and on the Polyatomicity of Acids*," by E. Frémy.

The importance of the phenomena relating to polyatomicity is well known to all the world; they interest equally in reference to mineral substances as well as organic bodies; they bear a strong relation to the study, so important, of isomerism.

In presence of a chemistry that is termed *modern*, and which brings into active play the polyatomic bodies, at the same time often forgetting the labours of former authors, M. Frémy reminds us that the first studies on polyatomicity date from the year 1797. Berzelius stated that M. Frémy was the first to introduce new ideas into the science of organic chemistry, which Mr. Graham had developed in his excellent work on phosphoric acid. Since that period the phenomena relating to the polyatomicity of acids have constantly occupied his attention, and he summed up the results of his researches in papers which he has published on metallic acids, hydrates, the gelatinous matters of vegetables, &c. The result is, that M. Frémy affirms that silicic acid can appear in two isomeric states which differ one from the other, not only by their physical properties, but also by their well-defined chemical constitution. They have not the same equivalent, and thus form different salts. The first isomeric state is that which is obtained in decomposing by water the fluoride of silicium. He calls it *metasilicic* acid; its equivalent is $(SiO_3)_3$, it is triatomic, and forms with bases the following three series:—

$$(SiO_3)_3MO,2HO$$
$$(SiO_3)_32MO,HO$$
$$(SiO_3)_33MO$$

This isomeric state is characterised by its solubility in alkaline solutions; it is not destroyed by combination with bases; the metasilicates can be separated, still retaining the same properties. The second isomeric state is that which constitutes quartz; its equivalent is SiO_3; it is insoluble in alkaline liquors, and it forms with bases salts which differ from the metasilicates by their characters and composition. M. Frémy stated, moreover, that he had obtained several of these salts in a crystallised state; they are represented—

$$SiO_3MO,2HO$$
$$SiO_32MO,HO$$
$$SiO_33MO \quad \text{(Peridot)}.$$

The silicic acid is thus triatomic, as the preceding, but it has not the same equivalent.

The principal aim of these researches is, then, to extend to silicic acid the theory that is set forth in former memoirs on the isomerism of acids. M. Frémy wishes to prove that for certain acids the isomeric states are due to different condensations of the molecules, which cause the equivalent of these substances to vary; he has essayed to connect the isomerism of the acid with the change which takes place in the volume of combination. He thinks that these ideas are productive of further research, and that they can explain the very variable constitution of natural silicates.

M. Chasles presented to the Academy, on the part of M. Zeuthen, of Copenhagen, a work originally written in Danish and translated into French, entitled, "*Nouvelle Méthode pour déterminer les Caractéristiques des Systèmes de Coniques.*" The subjects treated upon by M. Zeuthen relate to the theory of multiple contacts and the superior order of conics of a system defined by two characteristics with one or more curves of any order. On these thorny subjects the author has displayed much talent and judgment, without neglecting the rigour necessary in mathematical investigations.

M. Henry Saint-Claire Deville, in his name and that of M. Troost, presented a memoir on the coefficients of dilatation and the constitution of hyponitric acid. This acid presents in the state of vapour a constitution that has been always considered as perfectly normal, provided that its density is taken sufficiently far from its point of ebullition. But this density does not well enough agree with atomic speculation; for, if one would wish to double the formula NO_4, the density of the vapour of the hyponitric acid must be also doubled, which becomes embarrassing. In fact, the hyponitric acid must represent two volumes only, instead of four, admitted hitherto. To meet this difficulty, Messrs. Deville and Troost resolved to measure the coefficient of dilatation of this acid with all precautions in order to ascertain its density. We cannot to-day enter into the details of the process, so we confine ourselves to a rapid enumeration of the results arrived at. The numbers which give the coefficient of dilatation of hyponitric acid give evidence of an unforeseen fact, unknown before, that at a temperature of 40° the coefficient of dilatation attains its maximum value. They show, moreover, that, at about 135° C., the coefficient takes the value of 0·00367 of perfect gases, and does not vary sensibly in the space of 47°. One can even say that it is sensibly constant from 100° upwards, for from 100° to 183° it only varies from 1·68 to 1·57, while from 20° to 100° it varies from 2·65 to 1·68. Thus, the hyponitric acid vapours taken about 135° at a point sufficiently superior to that of ebullition is consistent with the law of Marriotte, and possesses the constant coefficient 0·00357 of the dilatation of perfect gases; the density of the vapour is necessarily 1,589, representing four volumes for the equivalent NO_4. If we wish, as M. Müller says, to double the formula by writing N_2O_8, four volumes of vapour must necessarily be added. Messrs. Deville and Troost refute the opinions of, first, M. Wurtz, that the hyponitric acid NO_4, representing two volumes, is certainly partially decomposed into binoxide of nitrogen and oxygen at the moment when the density amounts to four volumes; second, Messrs. Playfair and Wanklyn, that the densities of the acetic acid and the hyponitric can be doubled.

M. Frémy presented to the Academy, in the name of M. Henri de Parville, his interesting little volume entitled "Causeries Scientifiques," with 47 woodcuts, and published by Savy, a record of the progress of science and industry during the past year. The buildings and arrangements for the new Exhibition are faithfully described. Next come the newest facts relative to the discoveries lately made in astronomy, physics, mechanics, chemistry, medicine and physiology, natural history, and general subjects.

We may here mention another scientific work by Professor Deherain, of the same size (18mo), called the "Annuaire Scientifique," published by Victor Masson and Sons, and containing a valuable history of scientific events during 1866. It is not a *causerie*, but a collection of original articles written by separate and celebrated men, such as Guillemin, author of the excellent work called "Le Ciel;" Dr. Marey, Laureate of the Institute; G. Rayet, of the Paris Observatory; L. Simonin, the distinguished engineer and geologist; Dr. Trelat, &c. The chapter on the exhaustion of our coal-fields is due to M. Simonin, who is also the author of a chapter on the same subject. Both of these little volumes appear to have left nothing unrecorded of our scientific progress at home and abroad.

F. Moigno.

Pharmaceutical Society.—Benevolent Fund.—The dinner in aid of the above Fund will be held at Willis's Rooms, St. James's, next Wednesday, the 20th inst., at half-past six o'clock. The Committee, bearing in mind that the dinner is for a section of the trade only, have not selected a special chairman for the occasion; the President of the Society will therefore preside.

NOTICES OF BOOKS.

Lessons in Elementary Chemistry, Inorganic and Organic. By Henry E. Roscoe, B.A., F.R.S. London: Macmillan and Co. 1867.

Mr. Roscoe has succeeded in producing a volume that is interesting and equal throughout from the commencement to the appendix. The frontispiece is a great improvement upon similar prints in chemical text-books, being a very well executed chromo-lithograph, representing in their proper colours and bands the spectra of the metals of the alkalies and alkaline earths, from the drawings of Bunsen and Kirchhoff. The volume is arranged chiefly for the use of schools and younger students of chemistry at colleges, and we believe that it has been already adopted as the text-book at several of the universities and large public schools.

The contents of the volume possess several novelties, and originality is shown notably in the classification of the metals, although there is, of course, not much room for it in an elementary text-book. The metals are arranged in eleven classes; the rule chiefly followed in this system seems to depend on the sum of the physical properties of the metals, combined with their leading chemical relations, so that the latter are not exclusively used as a basis of classification. This makes all the difference between a natural and artificial system, and the experience of other sciences shows that by the latter a greater number of facts may be so remembered by the student. Some classes have always been recognised as being perfectly natural, but metals that form the connecting links in the intimate chain are not so easily dealt with. A sum of characters, however, seems safely to have been followed in the present case. Thus arsenic, antimony, and bismuth "form a class," because they are triatomic, and form a junction between the metals and *metalloids*, and closely resemble phosphorus in their properties. Other authors have classified together arsenic, antimony, and tin on purely chemical grounds. Now take the silver class, copper, mercury, and silver; the reasons that held for the grouping in the arsenic class do not apply here; on chemical grounds, copper and mercury are widely separated from silver on account of its monequivalency and non-formation of basic salts; but if we take into consideration the other properties of these metals, they are seen to fall naturally into the same class. Lead also forms a class with thallium, its close connexion with mercury being in this manner lost sight of.

This is a good field for graphic illustration, and we comment on it thus at length because we think it is not sufficiently insisted upon as a method of retaining knowledge. Perhaps this, however, may be done more advantageously by the student himself. As a high authority observes, "the student will do well to accept the order and arrangement of his teacher. As, however, minds are variously constituted, he can, if he pleases, try if some other order may not be more applicable—that is to say, he takes the facts he has heard and recorded, and reunites them in a different arrangement and in other words."

The descriptions are clear, with the nomenclature precise, throughout the work, and the amount of information to be obtained from it is shown by the kind of questions appended. Thus we find the following concise account of the oxides of manganese, with a detailed description following:—(1) *Manganous oxide* or *manganese monoxide*, MnO, is a basic body, furnishing the series of well-known manganous salts, in which the oxygen is replaced by its equivalent of another element or of a salt radical—thus $MnO, MnCl_2, MnSO_4, Mn_2NO_3$; (2) *manganic* oxide or *manganese sesquioxide*, Mn_2O_3, which also forms salts, but of a much less stable character, and occurs in nature as the mineral braunite; (3) *red* or *mangano-manganic* oxide, Mn_3O_4, a neutral body, corresponding to the magnetic oxide of iron, and occurring in nature as hausmannite; (4) *black oxide* or *manganese dioxide*, MnO_2, a neutral substance, occurring as the ore of manganese in the minerals pyrolusite and varvacite; (5) and (6) two compounds of manganese and oxygen, which have not been prepared in the anhydrous state, but of which the acids corresponding are known in combination as salts—thus we have K_2MnO_4 potassium manganate, and $KMnO_4$ potassium permanganate."

We may quote, as a type of the questions,

"*Lesson XXXVIII.*

"I. How does starch differ in constitution from glucose?

"II. What weight of dextrine and dextrose can be obtained from 1 kilo. of starch by the action of diastase?

"III. What is the composition of gun-cotton, and what advantages does it offer over gunpowder?

"IV. $C_{20}H_{27}NO_{11} + 2H_2O = C_7H_6O + HCN + 2C_6H_{12}O_6$. Explain the above equation.

"V. What is the composition of ink?

"VI. State some of the general characters of a glucoside."

We could not by our own words point out the merits of the book nearly as well as these extracts do themselves. There are plenty of works in English that can be read after it by the more advanced student; but it has no rival in its own field, and it can scarcely fail to take its place as the text-book at all schools where chemistry is now studied; and the science can now be taught by an ordinary master with little difficulty. We hope that a volume on practical chemistry will be provided also to be used with it, to prevent the science of chemistry being regarded as dry and difficult by those commencing the study of it.

We may add that the book is also well fitted for the junior chemical classes at the universities, colleges, and medical schools. Quite enough organic chemistry for the latter will be found, a third of the volume being devoted to it. A chapter on spectrum analysis, and on the principles of solar and stellar chemistry, is also given. In spite of the care with which the book has been got up, we notice still a few misprints in it—indeed, their non-appearance in any chemical work dealing with organic chemistry is hardly to be expected; and in a new edition, which we hope will soon be called for, these will doubtless be removed.

Hints on Spectacles. By W. Acland, Surgeon. London: Horne and Thornthwaite.

This pamphlet shows what is required to be considered in choosing a pair of spectacles. It has no pretensions to give any fresh information as regards optics or the physiology of the eyes, but will be very useful to those who, finding their eyesight failing somewhat, may wish to know the consequences attendant upon the use of glasses unfitted for them. Mr. Acland has done his work in a very satisfactory manner, and we hope that other opticians also will publish pamphlets, as Messrs. Horne and Thornthwaite have done in this case, to save trouble both to their customers and to themselves.

The matter of the pamphlet is very ably written, and is eminently practical. An account is first given of the anatomy of the eye, as regards its adjustment. Mr. Acland remarks:—"Anatomists, philosophers, and opticians differ as to the means employed by nature to effect such an important object, and although this question has been warmly discussed, each advocating their own pet theory, we are as yet far from the discovery of the cause, and must content ourselves with a knowledge of the result." The diagrams illustrating the different kinds of sight are excellent. The symptoms indicating a necessity for spectacles are so clearly laid down that not even a hypochondriac could mistake them. We agree with Mr. Acland that an optician should possess (1) an intimate

knowledge of the structure of the eye, and of the theory of vision; (2) an extensive acquaintance with the science of optics; (3) a sound mathematical knowledge; (4) a practical acquaintance with the manufacture of lenses and spectacle frames. Mr. Acland shows clearly that he possesses these qualifications, and justly observes—"As a proof that I possess the needful mathematical knowledge, I beg to refer, with some little pride, to a most complete set of formulæ relating to spectacles, now first published and given, and which are, in conjunction with Smee's optometer, used daily by myself with considerable success." A great practical point, as shown here, is to examine the lenses by polarised light to see if they be properly cut from the crystal. The principles of Smee's optometer and Smellen's types are made very clear. The short rules which are given for the preservation of sight and selection of spectacles should be read by everybody, especially persons who are obliged to use their eyes much owing to literary occupations. Thus all should know that irritation of the eyelid can easily be cured by red oxide of mercury ointment; that spectacles should only be used as compensatory agents; that spectacle frames should not be neglected; and that scratching of the lenses should be carefully guarded against. We also learn that single eye-glasses are injurious; that the eye should never view an intense light; a flickering light should be avoided; black objects should only ever be examined by daylight; people with weak sight should avoid the use of gas, and work with a properly constructed reading lamp; and reading during railway travelling should be always avoided. The good reasons for these hints are obvious, but it is as well to repeat them, as there is a great deal of difference between recollecting and remembering a fact. As will be judged from the above extracts, the pamphlet is eminently practical, and we think that few could read it without being convinced that they had learnt something fresh.

CONTEMPORARY SCIENTIFIC PRESS.

[Under this heading it is intended to give the titles of all the chemical papers which are published in the principal scientific periodicals of the Continent. Articles which are merely reprints or abstracts of papers already noticed will be omitted. Abstracts of the more important papers here announced will appear in future numbers of the Chemical News.]

CORRESPONDENCE.

Titration of Ethers.

To the Editor of the Chemical News.

Sir,—Your correspondent who writes about "Clairvoyance" was, perhaps, absent when my paper was read before the Chemical Society. I referred to Berthelot's researches at the beginning of my paper on the Titration of Ethers. I am, &c.

J. Alfred Wanklyn.

London Institution, February 12.

Determination of Phosphates in Superphosphate of Lime.

To the Editor of the Chemical News.

Sir,—One of your correspondents alludes to the loss of "soluble phosphates" by keeping in a pile. Is this a real loss of soluble phosphate that in any way deteriorates the manure? We have most of us been taught by agricultural chemists that all the soluble phosphate becomes insoluble within a few hours or days after the superphosphate is mixed with the soil, and that this is owing to the lime contained—in fact, that plants do not suck up the soluble phosphate as such, but that the phosphate of lime is presented to the root fibres in a finely divided state, as a gelatinous precipitate, as can be shown in a test-tube by adding ammonia or potassa to a solution filtered out of superphosphate of lime. Where gypsum is mixed with the superphosphate as a drier, the differences between the determinations of soluble phosphate in recently made samples and those from the same pile after keeping a few months are greater than where none is used. And, so far as my experience goes, the want of agreement between the reports of different chemists has reference to the gypsum used, for a "concentrated" superphosphate has always yielded the same percentage of soluble phosphate, whether under the hands of a "high" or a "low" analyst. I am, &c. Phosphorus.

Condensation of Noxious Vapours from Chemical Works.

To the Editor of the Chemical News.

Sir,—Chemical waste products are, as a rule, so easily fixed that it is a matter of serious complaint when a thing so easily done is not done, causing sickness and the greatest annoyance to every person in the neighbourhood of any chemical manufactory. The fault must be either in defective legislation or in a defective enforcing of powers already given as a protection to the public against annoyance by the chemical manufacturer. You would do me the greatest service by informing me of the exact state of the law on the subject, and also if anything further in this direction is now under discussion. I am living near an artificial manure manufactory, and in the vapours which are copiously evolved from the works, besides quantities of disgusting organic matter, may be found the following gases—SO_3, SO_2, SH_2, and FlH (from the fluor spar in the coprolites), as also, at times, a little HCl and salts. Now, will any of your readers, after looking at the above list, believe that gases capable of doing so much injury to vegetation and the health of all in the neighbourhood, even when in very small quantities, should not be absolutely fixed, and their escape so prevented? The manufacturers could easily do it if they wished, and the optional fixation of noxious gases should not be allowed by the Government.

When in the city of London last, I heard complaints of the effects of acid fumes as being injurious to respiration and clothing in the neighbourhood of one of the most perfectly conducted gold refineries that I have yet met with. If, then, dwellers in the city of London grumble in vain under such circumstances, what progress towards condensation of noxious vapours will chemical manufacturers make if every possible preventive means be not enforced?

I am, &c. Sufferer.

February 11.

MISCELLANEOUS.

Precautions against Cattle Plague in Holland.—As an instance of the very rigorous measures of precaution to prevent the cattle plague now raging in Holland from being carried over into Prussian territory, the following may serve:—Two lads, living in the Prussian portion of the village of Lobith (a portion of it is on Dutch territory), go to school at Elten, a village on Dutch territory about two miles from their residence; the greater part of their road is on Netherlands territory. On returning from school at night, these boys are subjected for fully one hour to a severe disinfecting process. The lads, annoyed at this, tried the other day to elude the vigilance of the Prussians by taking their way through fields. No sooner, however, had they entered upon Prussian territory than the soldiers on duty commenced firing their needle guns at them, and forced them to return and undergo the disinfecting process. You must know that, besides armed Custom-house soldiers, Prussia now keeps on the Netherlands frontier a strong military force to prevent parties getting across without quarantine, &c.—*Indépendance Belge*, February 9.

Fouling of Guns.—The following novel theory of fouling, which recently appeared in the *Engineer*, will amuse, if it does not interest, our readers:—"All who have been accustomed to take a routine view of the results of gunpowder explosion, assuming them to be simply made up of sulphur, potassium, carbonic acid, and nitrogen, will be astonished to discover that the preponderance of solid residue is not sulphide of potassium, but a mixture of carbonate and hydrate of potash. Any chemist will at once comprehend the importance of these materials in respect to the prevention of fouling, but to others not chemists the fact should be indicated that carbonate of potash is no other than pearlash, a saponifying agent when it comes into contact with grease or oil, and that hydrate of potash is a saponifying agent to a still higher degree. The small-arm rifleman, to whom the troubles of fouling are so familiar, will not be slow to comprehend the bearing of this fact. Given a competent supply of saponifying material, then, if the powder be good, the necessary materials will be supplied for the production of soap, through the operation of which the fouling will be reduced to practically inefficient limits."

Sanitary Laws.—The Council of the National Association for the Promotion of Social Science has lately paid considerable attention to the subject of the working of the public health laws. Every one who has come in contact with the gentlemen to whom their execution is entrusted, must have been astonished at the amount of good work that is done by them in spite of the many difficulties in their way, and have thought that the laws relating to such subjects must require great improvements for them to be more easily enforced. In fact, all sanitary officers find, more or less, that their power is very much cramped, unless some pestilence breaks out to frighten householders into attending to matters that at other times they do not feel any interest about. In the proposed memorial

drawn up by the Council, the more prominent of the evils of the system as a whole are shown to be as follows:—First, of general and local enactments, many of the latter are altogether out of place, and require transference to the former. By one section of one bill the penalty for selling diseased meat is 10*l.*, while for precisely the same offence, by a section of another bill, the fine is 20*l.* The memorialists, in the most moderate language, observe, "This of necessity leads to confusion." Again, many important enactments are permissive. The memorialists justly insist that "*the most useful* measures" should be peremptory. That may be all very well, but the simple expression of "a permissive nuisance" seems very illogical. All without exception should be on one footing, unless the law will consent to define a great nuisance as opposed to a little one. Nuisances should certainly be defined by law, and of course suppressed. If it be left to the opinion of the local authority to say whether this or that nuisance should be suppressed, the whole spirit of sanitary improvement is lost. Lastly, for sanitary reform, we want one "head centre" or head court which might compel the local authorities to do their duty. Thus the questions arising would not require reference to this or that court; and the provisions of one Bill (the Sanitary Act of 1866) would not then have to be carried out in one case by local authorities, in another by sewer inspectors, in a third by the police magistrates and justices, or, as in the case of the appointment of county analysts, by the Court of Quarter Sessions of every county. We think that the memorialists have shown sufficient sources of weakness in these laws to render any efficient administration of them next to impossible, and are sure that the following is a very moderate statement indeed; the literal truth would be much more severe:—"The local authorities are more or less *unlearned*, and for that reason require plain and specific directions. They are interested in diminishing the rates, and are, therefore, frequently unwilling to act in sanitary matters except under compulsion. They are often ignorant of the importance of sanitary precautions, and indifferent to the most flagrant nuisances."

Science and Public School Education.—At the Royal Institution, on Friday, February 8, the Rev. W. Farrar, M.A., a high authority on the subject, gave a most eloquent address "On Public School Education." Mr. Farrar's evidence on the subject is of great value, since the rev. gentleman has himself been trained, and has trained others, in the existing system. It was urged that the present system was not only passively, but actively, bad in its training influences on the mind, that England was the only civilised country where such a state of things was tolerated, and the comparison between the activity of science and lethargy of theology was fairly made. The lecturer did not go so far as to urge the abandonment altogether of the classics, but was strongly in favour of its giving way in part to science. He said truly that the clergyman of the present day could not venture to talk of the most elementary scientific facts to the ordinary artisan or workman, and that, in the self-sufficiency of his knowledge, "the young B.A. fresh from college found it easy to crush Darwin with a text." The lecturer, in conclusion, most eloquently named some of the great triumphs of physical and natural science, and denied indignantly that it encouraged a spirit of scepticism, remarking that, in this enlightened age, no religion could hold its own without a full study of science by its professors. It is a strange fact that the most forcible denouncers, past and present, of an exclusively classical education are, or have been, those who have had the largest experience of its working.

Editorial Courtesies.—Recently, commenting on an assertion that the iron trade was leaving us, the *Examiner* quoted, against such a belief, a statement of facts as from the *Mining Journal*. Thereupon the *Birmingham Daily Post* remarked:—"The quotation here given as from the *Mining Journal* was taken by that paper from our own leading columns, word for word, without acknowledgment." On which, down comes the *Iron Trade Circular* with, "The editor of the *Birmingham Daily Post* has omitted to mention that he took his facts and figures from us, and we may as well say that ours were supplied to us by the *Economist*."

Castor oil is as useful in the trades as it is as a medicine. It is much better to soften and to redeem old leather than any other oil known. When boots and shoes are greased with it, the oil will not at all interfere with the polishing afterwards, as is the case with lard, olive, or any other oil. In Harrisburg, Pennsylvania, the old leather hose of some of the fire companies was greased with it, and it was found to become almost as soft and flexible as new leather. Leather belts for transmitting motion in machinery will usually last three to five years, according to the wear and tear they are exposed to; when greased with castor oil, they will last ten or more, as they always remain flexible and do not crack. Besides this advantage, castor oil will prevent slipping, so that a belt three inches wide impregnated with it will be equal to a belt four and a half inches wide without castor oil. It is necessary, however, to wait twenty-four hours, till the oil has disappeared from the surface and penetrated the leather; otherwise the freshly-greased surface will cause slipping. That rats and other vermin detest anything impregnated with castor oil, and will not touch it, is another advantage.

Meetings for the Week.

ANSWERS TO CORRESPONDENTS.

*** All *Editorial Communications* are to be addressed to the Editor, and *Advertisements* and *Business Communications* to the Publisher, at the Office, 1, Wine Office Court, Fleet Street, London, E.C. *Private* letters for the Editor must be so marked.

F. L. O. P.—Thanks for your communication. It is, however, unsuitable for our columns.

J. W. S.—The articles will be resumed almost directly.

W. M B.—We do not advise the publication of your results in their present imperfect state. The process you describe could scarcely yield an acid sufficiently pure to analyse.

R. J. Tinniswood.—100 grains of pure dry carbonate of soda = 58·5 of oxide of sodium. This result is yielded whether the calculation is made with the formulæ and equivalents given in Fownes, according to the old notation, or whether the newest theory is adopted as given in Dr. Frankland's book. The result of 59·25 = oxide of sodium is therefore an error.

J. Stephens.—Arago's polarisation photometer is considered one of the best. It is much more complicated and troublesome than Bunsen's or Ritchie's, but we consider it gives more accurate results.

Books Received.—The Modern Practice of Photography, by R. W. Thomas, F.C.S.; Analysis, Purification, &c., of Coal Gas, by Rev. W. R. Bowditch, M.A., F.C.S.

Received.—Dr. Letheby; B. J. G.; R. C. C. L.; Child.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On the Methods employed to make sure of the Purity of Silver, by J. S. Stas.

In my "*Researches upon the Reciprocal Relations of the Atomic Weights*," I have stated that *pure silver may be fused and kept fused in air at a temperature sufficiently high to volatilise it without becoming at all stained or discoloured, and without giving off discoloured vapour.* I have taken this fact as a basis while seeking to ascertain the purity of the silver prepared by reduction from the chloride by means of potash and sugar of milk, or by reduction of *ammoniacal nitrate of silver* by means of sulphite of ammonium and ammoniacal cuprous sulphite. For this object about 400 grammes of silver from the chloride, placed in a crucible of lime from white marble, itself enclosed in a refractory crucible, were submitted to the *hissing* flame produced by the combustion of ordinary lighting gas in pure oxygen. *The silver fused without becoming in the least discoloured.* I then heated it until it boiled *violently*. The silver first gave to the flame the sodium character; but in a short time the yellow colour disappeared, and, so long as the silver did not boil, no discoloration appeared, although the metal gave off vapour in considerable quantity. After the silver boiled a *pale blue vapour* was produced,* which occasionally bordered upon purple.†

This vapour stained the lime a deep yellow, which colour, however, disappeared on the application of heat. When, by this species of refining, the silver must have lost all volatile matter, and when the fixed but oxidisable materials that it might contain must have united with the lime, I poured it from a good height, and in a thin stream, into distilled water, where it took the form of almost spherical globules of a pure white. The crucible presented no trace whatever of a metallic oxide or silicate.

The same treatment was applied to the pulverulent silver prepared by the cuprous ammoniacal sulphite, and identical phenomena presented themselves, excepting always the intense yellow colour of the flame, which was produced when the silver reduced from the chloride was heated to near its boiling point.

Before submitting the silver that I wished to test to the action of the oxyhydrogen gas-flame I took care first to expose the crucible of marble lime to the heat of the same oxyhydrogen gas, so as to eliminate as much as possible from the lime the volatile substances that give a particular colour to the flame. I observed on this occasion that all marbles contain notably *sodium*; that many contain *strontium* and *lithium*. By means of the method I am about to mention, I proceeded to the comparison of the refined silver with that from which it was derived, and with the typical silver prepared by the electrolysis of cyanide of silver and ammonium. Having been struck by the facility with which silver may be boiled violently, and distilled in the flame of *oxyhydrogen gas*, which MM. Henri Sainte-Claire Deville and De Bray‡ had before remarked, I wished to make use of it for the double purpose of procuring distilled silver, and at the same time to ascertain if silver refined as I have just shown still retains any traces of fixed bodies capable of uniting with lime.

For this purpose I had made in a block of lime, prepared from *white marble*, of from twenty-five to thirty centimetres in length, by ten centimetres width and height, a circular cavity three centimetres in diameter and two centimetres in depth, in communication with an inclined plane also three centimetres in width, by at most half a centimetre in depth, and serving to conde ise the vapour of silver. This inclined plane was terminated by a reservoir acting as a receiver for the liquid metal.

I placed about 50 grammes of refined silver in the cavity, first heated to whiteness by the application of a jet of lighted gas burning in a suitable excess of compressed air, and I covered the block with a plate of lime from white marble, five centimetres in thickness, pierced with two inclined circular openings, one corresponding to the circular cavity, the other to the little reservoir at the end of the inclined plane. Through one of the openings of the plate I passed one of the oxyhydrogen blowpipes of MM. Henri Sainte-Claire Deville and De Bray. This blowpipe had *very thick ends* of platinum to avoid their fusion, and the transportation of the metal. When the interior of the cavity had been heated to the boiling point of silver, not more than ten or fifteen minutes were required to distil the whole of the silver. *The 50 grammes were volatilised without leaving in the cavity of lime, which was used as the retort for distillation, the slightest appreciable residue to the eye assisted by a glass.*

I poured into distilled water the silver that I thus succeeded in obtaining in the receiver. The distillation of silver is such an easy operation to manage that I performed it three times. Nothing could be easier than to procure a kilogramme of silver, if the apparatus was proportioned to the mass. I must, however, admit that, in the operations I have described, *at least* half the silver used was lost. In fact it was carried away in the state of pale blue vapour by the current of oxyhydrogen gas, although this was very moderate, and without too great an excess of oxygen; it was diffused through the surrounding atmosphere, the transparency of which it affected, while imparting to it a very sensible metallic taste. My apparatus was also very imperfect; vapour of silver escaped in quantities by the opening intended to carry off the products of combustion, and all round between the block and the thick plate serving as a cover to it. Their surfaces, indeed, were not sufficiently well planed to fit very exactly.

Everywhere that the vapour of silver passed it left a light or dark yellow stain, like that left by the vapour of litharge.

The inclined plane, also, intended for the liquefaction of the silver vapour, was neither suitable in its form nor its dimensions to condense the whole of the metallic vapour carried off by the more or less compressed current of oxyhydrogen gas.

This detail is insignificant, since it resolves itself into a question of expense, which may be neglected in researches of this nature; but if a chemist should one day wish to renew with silver the series of determinations of the atomic weights, *it is to the volatilisation of the previously refined metal that I should advise him to have recourse to procure absolutely pure silver.*

Before concluding I must add that I noticed that the condensation of the vapour of silver takes place the more readily the less excess of oxygen the oxyhydrogen gas contains.

* Some chemists assign a *green colour* to the vapour of silver. The green colour observed arose indisputably from the copper contained in the silver submitted to the experiment.

† I attribute the purple colour to the existence of strontium or lithium in the marble used for the preparation of the quicklime crucible.

‡ *Annales de Chimie et de Physique*, vol. lvi. p. 413.

Contribution to our Knowledge of Osmium, by F. Wöhler, *Professor of Chemistry in the University of Göttingen.**

It seems to be universally admitted that in the substance obtained by melting osmium with caustic potash, the osmium is contained as osmic acid, OsO_4. This is not correct; for whilst, by the addition of acids, no precipitate takes place in a yellow aqueous solution of osmic acid in potash, but the latter changes colour; in the solution of the fused compound (whether nitrate or chlorate of potassium is used for oxidation), acids cause a strong black precipitate, with simultaneous formation of osmic acid. The compound produced by fusing contains, therefore, plainly a lower oxide, which, on being separated from the potash, falls as osmic acid and a black oxide. It cannot be osmious acid, OsO_3, discovered by Fremy, for the solution of the potash salt of the latter is violet, while the solution of the fused compound is a deep and clear yellow. By fusing ruthenium with caustic potash, without nitrate or chlorate of potassium, we obtain a dark brown mass which entirely dissolves in water with a deep orange-yellow colour. On the addition of nitric acid, as is well known, a black oxide falls, while the solution acquires a smell of ozone, apparently from ruthenic acid, RuO_4.

This similar behaviour of osmium and ruthenium is noteworthy, because it shows that if the two metals, as is usual, occur together, they cannot be separated in this way.

The subject deserves a still closer investigation. That which Claus says on the subject is not clear and decisive. He says,† "If a piece of caustic potash is dissolved in a solution of osmic acid (OsO_4), there results a blood-red solution, and KO,OsO_3 is formed quickly with evolution of oxygen. With great excess of potash there might be formed a superoxide of potassium, which gives off oxygen very slowly and almost imperceptibly. This red fluid still smells for a long time of osmic acid, until at length it loses the smell and changes its burning taste into a sweet compound of the salt KO,OsO_3; then the whole is changed into this salt without any reducing agent."

But then the solution must have become violet, which does not take place. I have never been able to perceive any evolution of oxygen. If we take caustic potash, we indeed see a feeble evolution of gas; but the fused hydrate of potash dissolves in water with a feeble evolution of gas. It would seem more probable that peroxide of hydrogen was formed, but I have not been able to perceive any.

I have also observed the following:—Sublimed osmic acid in excess was dissolved in solution of potash, and the deep reddish-yellow solution was allowed to evaporate spontaneously over hydrate of potash. There were formed wart-like opaque masses of crystals which were soluble in very little water with a reddish-yellow colour without leaving the least trace of the difficultly soluble violet osmite of potash. From this concentrated solution nitric acid precipitated white osmic acid, which, however, soon became grey, with a simultaneous precipitation of black oxide, whose amount gradually increased.

Metallic osmium was fused at a bright red heat with hydrate of potash. The black mass dissolved freely in water with a deep reddish-yellow colour. The solution by distillation in a retort was concentrated to one-fourth, whereby only very little osmic acid went over, and was allowed to remain closed up. In a short time a number of small octahedra of violet osmite of potash were deposited. A stream of pure carbonic acid gas was passed through the decanted yellow solution. It became first colourless, and then violet, with separation of a greyish-violet deposit and liberation of osmic acid. The deposit dissolved with a violet colour in much water, and left behind a little black oxide. From this solution a black oxide was precipitated by nitric acid, with formation of osmic acid. Carbonic acid acts in a similar manner upon the solution of the violet crystals.

If the black oxide is treated with concentrated hydrochloric acid, there results first a purple solution; it then becomes yellowish-brown, and lastly green. By heating it becomes brownish-yellow. With sulphuric acid it becomes a clear yellow, and also by boiling, but nothing is reduced. Zinc, however, precipitates the metal in black flakes.

On Boronatrocalcite, by Georg Lunge, *Ph.D.**

That interesting mineral which bears the names of boronatrocalcite, tiza, hydroboracite, tincalcite, rhodizite, and a great many others besides, but which is, perhaps, best known in this country by the somewhat unscientific name of borate of lime, has been the subject of investigations and analyses by a great number of chemists. Unfortunately, it never occurs in the pure state, but always mechanically mixed with, and often perfectly penetrated by, chloride of sodium, sulphates of sodium and calcium, etc. Besides, water has a decomposing action on this mineral.

It cannot be a matter of surprise, then, that no two analyses of it agree with one another—as will be seen from the very complete synopsis in Richardson and Watts' "Chemical Technology," vol. i. part iv. p. 209—and that also the ideas of different chemists about the real chemical formula of pure boronatrocalcite are very much at variance. Some declared it to be a borate of calcium containing sodium salts merely as a mechanical impurity; others took it for an accidental mixture of the borates of sodium and calcium; but more judicious inquirers found it to be a double salt of borate of calcium and borate of sodium. Especially the well-known chemist, Dr. Kraut, proved from many of the former analyses, and from his own, that by taking into account the never failing admixtures, and duly allowing for them in the calculation, the composition of boronatrocalcite can be reduced in those cases to the formula—

$$NaO,2BO_3 + 2CaO,3BO_3 + 15HO.$$‡

It is also a merit of Kraut's to have pointed out the unreliability of some of the former analyses—for instance, of Helbig's.§ Those chemists, of course, who did not find any sodium whatever, like Reichardt,‖ need not be taken into account at all. A simple glance at his figures, especially at the enormous percentage of boracic acid, is quite sufficient to settle that question. Rammelsberg¶ gives the formula

$$NaO,2CaO,6BO_3 + 18HO;$$

but it cannot be denied that the percentage of boracic acid in his own analysis falls too much short of that required by his formula, and agrees better with Kraut's. The only analysis, indeed, which decidedly gives

* Communicated by the author.

† *Archiv der Pharmacie*, 162, 25.

‡ I am using the old notation, both because Kraut is doing so, and because it is not yet very generally applied to mineralogical formulæ.

§ Liebig und Kopp, *Jahresber.* 1858, 737.

‖ *Eodem loco.*

¶ Liebig und Kopp, *Jahresber.* 1856, 884.

$2BO_3$ to the bases, is that of Helbig, and this cannot at all be relied upon, according to Kraut's showing, as mentioned just now.

I expected, accordingly, when I obtained some time ago a large quantity of boronatrocalcite for technical purposes, to find its composition agreeing with Kraut's formula, if I selected a very pure specimen and eventually allowed for the admixture of chlorides and sulphates. I found, in the first instance, that by taking only the central parts of the well-known nodules in which the mineral appears, I was able to prepare a sample perfectly free from chlorides and sulphates, and showing also no traces of sand, phosphoric acid, carbonic acid, aluminium, iron, or manganese; only boracic acid, sodium, calcium, and a very small quantity of magnesium. The latter apparently substitutes its equivalent of lime, as there is no other acid it could be combined with but boracic. I was, therefore, fortunate enough to be independent of all allowances for impurities, which may very easily lead into erroneous or disputable computations. In the second instance, I found my sample to be undoubtedly a biborate, while in Kraut's formula the ratio between the bases and boracic acid is 3 : 5. This occasioned me to analyse my sample, with the accuracy required for scientific results, in the following way:—

The mineral was digested for some time, according to Rose's prescription, with hydrofluoric acid in a platinum crucible; then pure sulphuric acid was added, and the mass was evaporated to dryness and ignited. Having cooled down, it was dissolved in hot water, acidulated with hydrochloric acid; the liquid was neutralised with ammonia, just acidulated with one drop of acetic acid, and the calcium precipitated by oxalate of ammonium. From the filtrate the magnesium was precipitated by phosphate of sodium. This mode of operating, in which the boracic acid is removed as fluoride of boron, appears unnecessarily troublesome, and was only followed to control my own simpler method—viz., simply to dissolve the mineral in dilute hydrochloric or nitric acid at a gentle heat, and to precipitate the calcium as oxalate from the solution containing all the boracic acid. The two estimations were entirely coinciding within the ordinary limits, and the expulsion of the boron appears, therefore, quite unnecessary.

The sodium is easily estimated by dissolving the mineral in a measured quantity of standard test acid (preferably hydrochloric or nitric acid) and remeasuring the excess of acid by a standard solution of alkali. The transition from the bright red colour of litmus caused by the strong acid into the purple caused by boracic acid, is perfectly sudden and accurately determinable. In this way is found the saturating capacity of all the bases combined with boracic acid; by deducting from this figure that corresponding to the calcium and magnesium previously estimated, there will be obtained a residue, which is to be calculated for sodium. The only objection to this method could be that the presence of potassium would make it inaccurate; but no trace of potassium could be found in my sample. Lastly, the quantity of water must be ascertained by igniting the mineral, and it can then be safely computed that all the rest not accounted for as water and as the oxides of sodium, calcium, and magnesium, is boracic acid. Of course, this is not allowable unless at least two analyses agree with each other, and unless a search for all other elements likely to interfere has been made; but if these conditions have been complied with, the computation of the residue for boracic acid is perfectly justified. A direct estimation would certainly be preferable; but a satisfactory direct method of determining boracic acid is still a desideratum of analytical chemistry.

My results were—Water, 36·89, 36·80, mean 36·85 per cent.; lime, 12·60 (estimated after the expulsion of boron), 12·78 (estimated directly from the acid solution), mean 12·69 per cent.; magnesia, 0·50 per cent.; saturating capacity of 1 gramme, 6·62, 6·54, mean 6·58 cubic centimetres of standard nitric acid. By deducting therefrom 4·53 (for 12·69 CaO) and 0·25 (for 0·50 MgO), there remains a residue of 1·80, corresponding to 5·58 NaO. On adding the mean percentages of water, soda, lime, and magnesia, the figure 55·62 is obtained, leaving 44·38 per cent. for boracic acid.

It is evident that the bases are combined with $2BO_3$, for then

12·69	Lime require	31·54	boracic acid.
0·50	Magnesia ,,	0·87	,,
5·58	Soda ,,	12·53	,,
		44·94	

a figure very nearly coinciding with that found above. The whole composition of the mineral agrees almost completely with the formula—

$$2(NaO,2BO_3) + 5(CaO,2BO_3) + 42\ aq.,$$

only with the substitution of magnesium for a small quantity of calcium.

In the following table a compound equivalent for lime and magnesia has been introduced, computed from the ratio of Ca : Mg = 18 : 1—

	Equivalents.	Calculated.	Found by analysis.	Required by Kraut's formula.
2NaO .	62·	5·82	5·58	7·83
5 { CaO, MgO }	138·	12·95	13·19	14·14
$14BO_3$.	487·2	45·74	44·38	43·94
42HO .	378·	35·49	36·85	34·09
	1065·2	100·00	100·00	100·00

It is obvious that Kraut's formula cannot be applied to my sample, and that my own formula agrees with the results of the analysis within reasonable limits. The deciding point is the saturating capacity of the bases; Kraut's formula requires 7·58 cubic centimetres standard acid for 1 gramme, my formula 6·51; and I found, as mentioned above, 6·62, 6·54, mean 6·58. It is perhaps worthy of remark that all formulæ, Rammelsberg's, Kraut's, and my own, give three equivalents of HO to each equivalent of BO_3.

I may be permitted to state that I published the analytical results detailed here in the *Annalen für Chemie und Pharmacie*, of April last year.** In consequence Dr. Kraut wrote to me to ask for a sample of my material. Between this request and my analysis six months had elapsed, and my stock of boronatrocalcite had been used up for technical purposes, except a few ounces, out of which I sent a sample to Dr. Kraut. Of course, this could not be so well isolated from the admixtures as my former one had been, and, indeed, Dr. Kraut found in it†† 6·72 per cent. of chloride of sodium and 4·74 sulphate of sodium. However, starting from the saturating capacity of the sample, which he found equal to 23·27 SO_3 (= 5·82 cubic centimetres standard acid), he assumed it to contain 88·54 per cent. boronatrocalcite, according to my formula; and his estimation of lime agrees exactly with this assumption, for he found, as a mean of three estimations, 11·57 CaO instead of 11·51, as required by 88·54 per cent. mineral

* Vol. 138, p. 51.
†† *Annalen der Chemie und Pharmacie*, 139, 52.

of my formula, by computing the small quantity of magnesium as its equivalent of calcium. His analysis is therefore a complete affirmation of mine in all its essential parts, and proves my formula to be correct. This case is, then, the first one, established beyond doubt, in which a specimen of boronatrocalcite showed $2BO_3$ to each equivalent of calcium and sodium. Would the surmise be quite unjustified, that my specimen represents the mineral in its original state, not having yet experienced any loss of boracic acid by extraneous causes?

TECHNICAL CHEMISTRY.

The Manufacture of Salt.

Our attention has been called to the following extract from a work entitled, "The Resources, Products, and Industrial History of Birmingham and the Midland Hardware District," 1866. Mr. Samuel Timmins is editor, but the name of the author of the chapter on salt is not given.

When factory and other operatives receive so much legislative attention, it is only fair to remember these neglected saltmakers of Worcestershire.

Solution and crystallisation are so interesting to chemists that we think it probable that mention of this subject in the Chemical News will bring a large amount of attention.

"The social condition of the saltworkers has for centuries been, and in most cases continues to be, a reproach to English civilisation. The heat of the stoves and pan houses in which they work, and which frequently better deserve the name of their homes than the miserable hovels in which they huddle out of working hours, renders more than a minimum of clothing unnecessary, if not burdensome, and even this minimum is not unfrequently dispensed with by both sexes. The work is necessarily continuous day and night, and from Monday morning to Saturday evening it often happens that the labourer never quits the precincts of the works, snatching his intervals of rest beside the pans. Men and women, boys and girls, are thus exposed to more than all the debasing and demoralising influences which haunt the worst dwellings of our agricultural labourers, without a single antagonistic agency to prevent their lapse into the lowest depths of brutish immorality. The social condition of the saltworkers has consequently been, and probably still is, more abjectly degraded than that of any other class equally numerous, although their poverty is by no means so depressing. With scarcely an exception, wherever salt manufactures on a large scale have existed, the population employed in them has been the disgrace and pollution of the neighbourhood, a community almost unapproachable by philanthropy and irreclaimable by religion. Happily we are able to record the dawn of better days in the district nearest to Birmingham.

"It is now eight years since the employment of women at the Stoke Works was entirely discontinued by the proprietor, John Corbett, Esq., and although the full result of the measure will not be felt until a new generation has arisen, it has already acted on the habits and condition of the workpeople in such a manner as to produce a social revolution in the neighbourhood. Marriage, an institution previously almost ignored, has, in a great measure, superseded the indiscriminate concubinage resulting from the former conditions of labour; the dwellings of the workpeople, now continuously occupied, have very perceptibly improved; and if the condition of the saltworker, from a social and moral point of view, is still greatly lower than that of the average artisan, it is far higher than it ever has been, or, indeed, could be, under the old system. The reformation thus effected has also been materially aided by an alteration in the arrangement of the work introduced about five years ago. Formerly, one man only was usually appointed to take charge of each pan both by day and night, and was paid at the rate of 1s. 10½d. per ton of salt manufactured. In place of this system, what is termed 'shift work' is now universally adopted at the Stoke Works. Two men, one for the day and one for the night, are appointed to each pan, and receive 2s. per ton proportionally divided between them, the higher rate of payment being compensated by the additional amount manufactured under the new system. Three assistants are required to each pan, who are paid by the men in charge of it out of their receipts for the salt manufactured. Much of the work can be done by boys and girls, and a father, by taking his children as his assistants, could make a considerable addition to his wages. A strong inducement is thus held out to parents to employ their children in such a manner as wholly to preclude their chance of obtaining any education, although at Stoke the inducement no longer exists in the case of girls. All the work is paid by the piece, and even in processes apparently so simple an amount of judgment, experience, tact, and dexterity is required which makes a wide difference between the wages of a good and a bad workman. A fair workman, on an average, at 2s. per ton, can, it is calculated, make about 28s. per week. Each head of a pan is paid 22s. weekly on account, and the balance is settled monthly, the work being appraised by the foreman of the salt works, who rejects or reduces the allowance for work in any way faulty or imperfect. About 500 hands are employed at Stoke Works, and the average amount of salt of all kinds manufactured is about 3000 tons per week, with a consumption of from 1500 to 2000 tons of fuel.

"Previous to 1823, when the duty on salt, then as high as 15s. per bushel, was repealed, the entire annual produce of Droitwich did not amount to more than 9000 tons, the entire produce of Worcestershire being now about 200,000 tons per annum. The Cheshire salt works are capable of producing 1,000,000 tons per annum, but the supply being immensely in excess of the demand, many works are always standing still, both in the Cheshire and Worcestershire districts. The export trade of Worcestershire is about 50,000 tons annually; that of Cheshire about 650,000 tons.

"The price of salt for many years has ranged within very narrow limits. Monthly meetings are held by the manufacturers, as in other trades, and arrangements are made as to the rate of wages, the prices to be charged, and other matters affecting their common interests. The number of 'small masters' in the trade, however, renders any effective combination among the manufacturers as difficult as the introduction of any substantial reform in the habits and condition of the workpeople. A large portion of the trade in the aggregate at Droitwich is in the hands of such masters, who, not possessed of sufficient capital to undertake the manufacture on a scale large enough to permit the adoption of expensive improvements in machinery, or in the system of working and payment of wages, are still able, by employing their own family as workpeople, to produce salt at a rate so low as to render it difficult for those able to initiate the necessary reforms to realise an adequate remuneration from them. On the whole, there-

fore, although the experiment tried at Stoke has, we believe, been commercially as well as socially successful, and must in the long run materially affect the condition of the saltworkers, there is but little immediate prospect of their making any great general advance in the social scale. For the present the public is able to purchase salt at a price possibly lower by some infinitesimal fraction than it would be if the manufacture were entirely in the hands of large proprietors and the employment of women and children strictly prohibited; but the advantage is dearly purchased by the continued existence amongst us of a class of labourers which ranks below that even of the working colliers."

PHYSICAL SCIENCE.

On the Augmentation of the Power of a Magnet by the Reaction thereon of Currents induced by the Magnet itself, by* Charles Wheatstone, *F.R.S.*

The magneto-electric machines which have been hitherto described, are actuated either by a permanent magnet, or by an electro-magnet deriving its power from a rheomotor placed in the circuit of its coil. In the present note I intend to show that an electro-magnet, if it possess at the commencement the slightest polarity, may become a powerful magnet by the gradually augmenting currents which itself originates.

The following is a description of the form and dimensions of the electro-magnet I have employed. The construction, it will be seen, is the same as that of the electro-magnetic part of Mr. Wilde's machine.

The core of the electro-magnet is formed of a plate of soft iron, 15 inches in length and $\frac{1}{2}$ inch in breadth, bent at the middle of its length into a horseshoe form. Round it is coiled, in the direction of its breadth, 640 feet of insulated copper wire $\frac{1}{12}$ inch in diameter. The armature, which is according to Siemens' ingenious construction, consists of a rotating cylinder of soft iron, $8\frac{1}{2}$ inches in length, grooved at two opposite sides, so as to allow the wire to be coiled upon it longitudinally; the length of the wire thus coiled is 80 feet, and its diameter is the same as that of the electro-magnet coil.

When this electro-magnet is excited by any rheomotor, the current from which is in a constant direction, during the rotation of the armature currents are generated in its coil during each semi-revolution, which are alternately in opposite directions; these alternate currents may be transmitted unchanged to another part of the circuit, or, by means of a rheotrope, be converted to the same direction.

If now, while the circuit of the armature remains completed, the rheomotor be removed from the electro-magnet, on causing the armature to revolve, however rapidly, it will be found, by the interposition of a galvanometer or any other test, that but very slight effects take place. Though these effects become stronger in proportion to the residual magnetism left in the electro-magnet from the previous action of a current, they never attain any considerable amount.

But if the wires of the two circuits be so joined as to form a single circuit in which the currents generated by the armature, after being changed to the same direction, act so as to increase the existing polarity of the electro-magnet, very different results will be obtained. The force required to move the machine will be far greater, showing a great increase of magnetic power in the horseshoe; and the existence of an energetic current in the wire is shown by its action on a galvanometer, by its heating 4 inches of platina wire ·0067 inch diameter, by its making a powerful electro-magnet, by its decomposing water, and by other tests.

The explanation of these effects is as follows:—The electro-magnet always retains a slight residual magnetism, and is therefore in the condition of a weak permanent magnet. The motion of the armature occasions feeble currents in alternate directions in the coils thereof, which, after being reduced to the same direction, pass into the coil of the electro-magnet in such manner as to increase the magnetism of the iron core; the magnet, having thus received an accession of strength, produces in its turn more energetic currents in the coil of the armature, and these alternate actions continue until a maximum is obtained, depending on the rapidity of the motion and the capacity of the electro-magnet.

If the two coils be connected in such manner, that the rectified current from the coil of the armature, passes into the coil of the electro-magnet, in the direction which would impart a contrary magnetism to the iron core, no current is produced, and consequently there is no augmentation of magnetism.

It is easy to prove that the residual magnetism of the electro-magnet is the determining cause of these powerful effects. For this purpose it is sufficient to pass a current from a voltaic battery, a magneto-electric machine, or any other rheomotor, into the coil of the electro-magnet in either direction, and it will invariably be found that the direction of the current, however powerful it may eventually become, is in accordance with the polarity of the magnetism impressed on the iron core.

If, instead of the currents in the coil of the rotating armature being reduced to the same uniform direction, they retain their alternations, no effects (or, at most, very small differential ones) are produced, as no accumulation of magnetism then takes place.

I will now call attention to the fact that stronger effects are produced at the first moment of completing the combined circuit than afterwards. The machine having been put in motion, at the first moment of completing the circuit four inches of platina wire were made redhot, but immediately afterwards the glow disappeared, and only about one inch of the wire could be permanently kept at a red heat. This diminution of effect was accompanied by a great increase of the resistance of the machine. The cause of the momentary strong effect was that the machine, from its acquired momentum, continued its motion for a few seconds, though it required a stronger force than could be applied to maintain that motion. Each time the circuit is broken and recompleted, the same effect recurs.

On bringing the primary coil of an inductorium (Ruhmkorff's coil) into the circuit formed by connecting the coils of the electro-magnet and rotating armature, no spark occurs in the secondary coil. On account of the great resistance of the circuit, which now also includes the primary coil of the inductorium, the current is not in sufficient quantity to produce any noticeable inductive effect.

A very remarkable increase of all the effects is observed when a cross wire is placed so as to divert a great portion of the current from the electro-magnet. The four inches of platina wire, instead of flashing into redness and then disappearing, remains permanently ignited. The inductorium, which before gave no spark, now gave

* Communicated by the author, having been read at the Royal Society, February 14, 1867.

one half an inch in length. Water was more abundantly decomposed, and all the other effects were similarly increased.

I account for this augmentation of the effects in the following way:—Though so much of the current is diverted from the electro-magnet by the cross wire, the magnetic effect still continues to accumulate, though not to so high a degree; but the current, generated by the armature passing through the short circuit formed by the armature branch and cross wire, experiences a far less resistance than if it had passed through the armature and electro-magnet branches; and though the electromotive force is less, the resistance having been rendered less in a much greater proportion, the resultant effect is greater.

I must observe that a certain amount of resistance in the cross wire is necessary to produce the maximum effect. If the resistance be too small, the electro-magnet does not acquire sufficient magnetism; and if it be too great, though the magnetism becomes stronger, the increase of resistance more than counterbalances its effect.

But the effects already described are far inferior to those obtained by causing them to take place in the cross wire itself. With the same application of force 7 inches of platina wire were made redhot, and sparks were elicited in the inductorium 2¼ inches in length. The force of two men was employed in these as well as in the other experiments. When the interruptor of the primary coil was fixed, the machine was much easier to move than when it acted; for when the interruptor acted, at each moment of interruption, the cross wire being as it were removed, the whole of the current passed through the electro-magnet, and consequently a greater amount of magnetic energy was excited, while at the intervals during which the cross wire was complete, the current passed mainly through the primary coil.

The effects are much less influenced by a resistance in the electro-magnet branch than in either of the other branches. To reduce the length of the spark in the inductorium, the primary coil of which was placed in the cross wire, to ¾ inch it required the resistance of 5¼ inches of the fine platina wire in the cross wire, 5 inches in the armature branch, and 4 feet in the electro-magnet branch.

When there was no extra resistance in either of the branches, the length of the cross wire being only about a few feet, the intensity of the current in the electro-magnet branch compared with that in the cross wire was as 1 to 60, and when the resistance of the primary coil of the inductorium was interposed in the cross wire the relative intensities were as 1 to 42.

In conclusion, I will mention that there is an evident analogy between the augmentation of the power of a weak magnet by means of an inductive action produced by itself, and that accumulation of power shown in the static electric machines of Holtzman and others, which have recently excited considerable attention, in which a very small quantity of electricity directly excited is, by a series of inductive actions, augmented so as to equal and even exceed the effects of the most powerful machines of the ordinary construction.

To Recognise Wood Fibre in Paper.—The paper which is suspected to contain wood fibre is touched with ordinary strong nitric acid. If wood be present it is coloured brown, especially on warming. This reaction is more delicate than that with sulphate of aniline.—*M. Behrend, in Polyt. Notizbl.*, 1866, p. 288.

FOREIGN SCIENCE.

(From our own Correspondent.)

Paris, February 19, 1867.

On the occasion of an incident of which we shall presently say a few words, we must allow ourselves to protest against a mania which has passed into the state of an intolerable abuse. As soon as any new question of importance is here raised, it is referred for examination to a commission; thus far there is nothing to complain of. But what we cannot comprehend is, that the members of the commission are chosen from so restrained a circle of administrative, scientific, and industrial notables, that the commissions which succeed each other are almost always composed of the same privileged persons. It thus happens, without noticing, that one same French *savant* forms part of a thousand different commissions—governmental, municipal, academical, financial, economical, agricultural, &c. If we were to mention the names of the commissions or the committees to which, for example, M. Dumas belongs, almost always in the quality of president, one would really be frightened; perhaps we should exceed the number of 1000, which seemed just now a hyperbola. Incontestably no one can be more *au courant* of the scientific progress in all its forms—nobody more enlightened than M. Dumas, nor more devoted to the interests of the country; but his science and devotion do not give him the gift of ubiquity, and his working day, like that of other mortals, consists at most of ten or twelve hours. To accept the post of member of a commission is to impose a certain duty upon one's self—to engage the conscience. How, therefore, can any man's permit him to so multiply his functions and his duties that it amounts to an absolute impossibility to fulfil even the thousandth part? One can scarcely believe how serious are the inconveniences of this lamentable monopoly; how many interests of great importance are often thus left in sufferance; how many honourable private interests are thus fatally abandoned or put in peril. Let us allow facts to speak for themselves.

There is in France a society unique of its kind—the Society of Encouragement for National Industry, founded in 1804, and recognised as an establishment of public utility since 1824. Thus it is considerable from the number of its members, the composition of its council, and the choice of the judges of the committees. It was formerly rich, when the editing and printing of its bulletin did not absorb a great portion of its resources. Its first president was the chemist and minister, Chaptal, who was replaced by the great name of M. Thénard. It has for actual president M. Dumas, the man, in fact, the best in a position to render it prosperous and glorious, if he could devote to it a sufficient portion of his valuable time; but the presiding at the Society of Encouragement is but the hundredth part of the presidencies of M. Dumas, and how to bring forward so many occupations which exclude one another. The fortunes, the force, the soul—if we may so call it—of the Society of Encouragement are the annual public meetings for the distribution of gold, platinum, bronze, and silver medals to industrials and inventors, diplomas of honour to foremen and workmen, &c., &c., in which also it regulates its balance-sheet and annual budget. If it wished, the Society could hold two solemn meetings, but its regulations imperatively require one, and the occasional reading of the reports, as well as the distribution of the prizes, are a sacred right for the interested parties who have submitted their discoveries or works to its judgment. To frustrate them is an injustice which can be calculated in money, for the different distributions of each annual meeting amount to, in the average, more than 400*l*. But in order that the Society can hold its annual meeting the President must be able to devote two mornings to assist at the general meetings of the committees for the awarding

of the medals, and an evening for their distribution. Thus, when one is member of 1000 commissions, committees, and societies, two mornings and an evening free, are, we repeat, an absolute impossibility, and that it happens that the year passes without the annual meeting of the Society of Encouragement, to the great detriment of the progress of industry and the arts, to the great injury of industrials and inventors, to the great lessening of the Society which cannot attract to it members and capital, except it shows itself lively and just to those who place their hopes in it. The absorption of the person of the President, M. Dumas, has been the cause that no annual meeting took place in 1853, 1855, 1859, 1861, 1863, 1866, and has thus frustrated for ever, or a time, the works, or the persons, or the objects of the reports, of a sum of more than 24,000*l.*, without taking into account the immense discouragement caused by these disastrous irregularities. But here is the worst part of this business. Making a generous effort, the committee had everything prepared for the Society to repair, in the first days of 1867, its negligence and silence of 1866. After much consideration, the honourable President thought that he could dispose of the evening of February 6, and fixed the annual meeting for that day. The good news was inserted in the *Moniteur Universel* of Friday, the 2nd, and repeated by all the papers. Letters of invitation were addressed to all who waited for so long a time for their rewards. And some of them who hastened to be present had the disappointment to read in the *Moniteur* of Monday, February 4, that the President, hindered from coming, had postponed the public meeting to February 20; that he, consequently, made the public wait fifteen long days, and that the weekly meeting of February 6 was confiscated. It is an unpleasant task for us to make these painful revelations, and we are ashamed to say that these acts should take place in France, the leading country in science, which would not be for an instant tolerated in any other country; and the more we feel grieved since no one more than us can have more admiration, respect, and affection for M. Dumas; but for us who have for so many consecutive years waited for the labours of the Society of Encouragement to come to a successful issue, it is obligatory to speak so as to render impossible henceforth the continuation of treatment so disheartening.

The Paris Exhibition of 1867.—Great International Lecture-hall.

We feel ourselves bound to realise an idea conceived by the Imperial Commission which will give the most ample satisfaction to scientific visitors of the Exhibition of 1867. The opening of a great lecture-hall like this, in which all sciences and arts will be prominently displayed by the most celebrated men, will certainly be the grandest effort of modern progress in science.

The main portion of the Exhibition, containing a collection of machines, apparatus and products of all nations, requires a vivifying soul to illustrate all the objects therein and to reveal the whole contents of the palace to the world one after the other. This lecture-hall, vast and well lit up—in the day by elegant stained windows, and in the night by electric, Drummond, magnesia, and magnesium, and by gas light in all its principal forms, applied in all apparatus hitherto invented—is to form an integral portion of the Exhibition. We have obtained the faculty of giving admission in the hall, with right of insertion in the catalogue, and of competing for all the prizes, for all industrials who could not obtain room in the space reserved for their specialty on account of their application being too late. Arranged as an amphitheatre, the hall can contain 500 persons, comfortably seated, with proper ventilation, cool air, &c., by the latest known scientific means.

To give a sketch of what is to be treated on in this interesting building on a thousand different subjects, both national and international, the following is the programme.

National Conferences.—These are to consist of historic and technical discourses.

Historical Lectures.—1. General history of progress under all its forms. 2. History of the principal branches of science, industry, and fine arts, illustrated by portraits of savants, inventors, and illustrious men.

Technical Lectures.—1. Exhibition of products or objects, under the eye or by the aid of photographic views, magnified and projected on a vast screen, the original works of the Universal Exhibition, to suit the lecturers. 2. Lectures given by exhibitors, or in their name, in order to bring their inventions, &c., before the public, or their services rendered for the public good.

International Conferences in French, or in the Language of other Nations.—1. Patriotic lectures required by the Commissioners of the different Governments. 2. Lectures on the progress of science, industry, and the arts, given by special lecturers; individual conferences solicited by the exhibitors.

The administration of the hall purpose being a sort of intermediary between the producer and the consumer, between the inventor and the manufacturer. Also, there will be ample means for the sale of products, patents, licences, &c., so as to render eminent services to all classes of exhibitors. This institution, the initiative of which emanates from the Imperial Commission, will certainly become a favourite place of resort, and we have reason to believe that it will be filled several times every day.

The lectures, printed and completed by the addition of supplementary pages, will contain the most faithful account of the progress accomplished and brought to light in the great enclosure of the Champ de Mars; so we hope that all inventors and industrials of the United Kingdom will give us an opportunity of distributing printed or manuscript documents which they will have to produce relative to their rights to the recompenses of the juries. They can be addressed to the office of this paper 1, Wine Office Court, Fleet Street, London, E.C.

Respiratory Apparatus and Obturators of Gas-pipes of M. Galibert.—This apparatus has become very popular in France and England. Public experiments have been made with it at Paris, London, Southampton, Cherbourg, Toulon, Brest, and many other towns, and the success has been wonderful. Its object is to protect life from the dangers of an irrespirable medium, no matter of what nature; penetrating and thick smoke, nitrous, sulphurous, or carbonic acids; sulphuretted hydrogen, nitrogen, coal gases, &c. It is composed essentially of a reservoir of air formed of a tissue, completely impermeable, which the operator carries with him wherever he wishes to enter. At first the reservoir was formed of goat-skins, similar to those which serve in Italy, Spain, the South of France, &c., for containing wine or oil. These sacks, from the great success of the apparatus, becoming more and more rare and dear, M. Galibert was obliged to have recourse to cylinders for artificial tissue, perfectly impermeable, and very strong, which he prepares by glueing together two strong linen and hemp cloths, each coated with eight layers of india-rubber varnish. They are filled in a few seconds by means of a small bellows, and are capable of containing eighty litres of air; they are carried on the back of the operator, like a knapsack, by means of straps. The communication between the air in the reservoir and the mouth and the respiratory organs is made by two tubes of india-rubber fixed, that of aspiration at the bottom of the reservoir, and that of expiration at the top of the bag, both tubes terminating in a sort of mouth-piece, which the operator places between his teeth. A strong clip prevents breathing by the nostrils, and the eyes are protected by two concave glasses set in a circular band of leather, which surrounds the head, and shuts hermetically. Thus provided with air, the operator can penetrate, and remain, without suffering, in the most mephitic and constant atmospheres. If his sojourn should

be further prolonged, he can carry with him several cylinders for exchange ready filled. He carries also suspended at his waist, which sounds on the hand being pressed against it, an india-rubber ball or tube, in case of danger. This respiratory apparatus has been definitively adopted by the companies of the Sapeurs-Pompiers or fire brigade of Paris, and of many departments, by several mining companies, the municipal administration of Paris, the General Gas Company, the Navy, &c., &c. It is absolutely indispensable for well-sinkers, sewerage workmen, those who repair the gas mains, &c.; also to those who are forced to penetrate into places where fermentation is going on, in distilleries of grain, or in manufactories of chemical products, or other industries where chlorine, nitrous acid, muriatic acid, or sulphuretted hydrogen abound. What frightful accidents might be avoided if the respiratory apparatus of M. Galibert, so simple, so efficacious, so economical, were, as it ought to be, generally adopted! The artificial tissue of M. Galibert is destined to render immense service in a great number of cases. A new application of it has been recently made. When a gas main has to be repaired, it is necessary to close the end of the tube next to the gasworks. The general practice is to close it up by an india-rubber sack or ball, uninflated, introduced into the aperture of the tube, and afterwards filled with compressed air by means of bellows. This system is attended with much difficulty. M. Galibert has proposed to M. Guiffrer and M. Lependry, directors of the General Gas Company of Paris, to substitute for the india-rubber balloons, cylinders of impermeable cloth, 30 to 50 centimetres long and of a convenient diameter, which, inflated with air, fill the cavity of the gaspipe and close it much more hermetically. The experiment was made on two tubes of different diameters with complete success. The obturator cylinders support a pressure double that at which the india-rubber globes yield without allowing the gas to pass, and retain 60 per cent. of the gas which the india-rubber stoppers let escape. The result is that for the town of Paris alone the substitution for the india-rubber balls of the cloth cylinders of M. Galibert, much less costly and incomparably more solid, effects an annual economy of more than 600*l*. Let us repeat again that the discovery of a tissue utterly impermeable to air, and very resistent, is an industrial achievement which is of great promise.

F. Moigno.

PROCEEDINGS OF SOCIETIES.

ROYAL SOCIETY.

Thursday, February 14, 1867.

General Sabine, *President, in the Chair.*

A paper was read "*On the Conversion of Dynamical into Electrical Force without the aid of Permanent Magnetism*," by C. W. Siemens, F.R.S. The apparatus employed in this experiment was an electro-magnetic machine consisting of one or more horseshoes of soft iron surrounded with insulated wire in the usual manner, of a rotating keeper of soft iron surrounded also with an insulated wire, and of a commutator connecting the respective coils in the manner of a magneto-electrical machine. If a galvanic battery were connected with this arrangement, rotation of the keeper in a given direction would ensue. If the battery were excluded from the circuit and rotation imparted to the keeper in the opposite direction to that resulting from the galvanic current, there would be no electrical effect produced, supposing the electro-magnets were absolutely free of magnetism; but by inserting a battery of a single cell in the circuit, a certain magnetic condition would be set up, causing similar electro-magnetic poles to be forcibly approached to each other, and dissimilar poles to be forcibly severed alternately, the rotation being contrary in direction to that which would be produced by the exciting current.

Instead of employing a battery to commence the accumulative action of the machine, it sufficed to touch the soft iron bars employed, with a permanent magnet, or to dip the former into a position parallel to the magnetic axis of the earth, in order to produce the same phenomenon as before. Practically it was not even necessary to give any external impulse upon restarting the machine, the residuary magnetism of the electro-magnetic arrangements employed being found sufficient for that purpose.

The mechanical arrangement best suited for the production of these currents was that originally proposed by Dr. Werner Siemens in 1857,* consisting of a cylindrical keeper hollowed at two sides for the reception of insulated wire wound longitudinally, which was made to rotate between the poles of a series of permanent magnets, which latter were at present replaced by electro-magnets. On imparting rotation to the armature of such an arrangement, the mechanical resistance was found to increase rapidly to such an extent, that either the driving-strap commenced to slip, or the insulated wires constituting the coils were heated to the extent of igniting their insulating silk covering.

It was thus possible to produce mechanically the most powerful electrical or calorific effects without the aid of steel magnets, which latter were open to the practical objection of losing their permanent magnetism in use.

The reading of this paper was followed by one "*On the Augmentation of the Power of a Magnet by the Reaction thereon of Currents induced by the Magnet itself*," by Professor Wheatstone, F.R.S. (see page 89). An animated discussion on these two papers followed.

CHEMICAL SOCIETY OF PARIS.

November 2, 1866.

M. Berthelot *in the chair.*

M. Schutzenberger announced that M. Bolley, who had hitherto disputed the formula of purpurine assigned by him, now admitted the formula $C_{10}H_6O_7$, which made purpurine an oxidation product of alizerine. There still existed a disagreement between M. Schützenberger and M. Bolley as to the constitution of the yellow colouring matter derived from alizerine. M. Schützenberger maintained his original opinions.

M. Berthelot stated that he had conducted further experiments on the action of potassium on hydrocarbons. Not only was acetylin, but cumol and naphthalin also were attacked by the alkali metal. The same might be said of reten, anthracen, and in general of the less hydrogenised hydrocarbons. Benzol and many other hydrocarbons rich in hydrogen are not attacked. M. Berthelot then explained his researches on the action of heat on hydrocarbons. (These have already been described in the Chemical News.)

M. Personne stated that, in the torrefication of caffein or coffee, a considerable quantity of salts of methylamine was formed.

M. Albert Roussille showed some characteristic reactions of the salts of rosaniline and rosaloluidine.

M. E. Willin presented in the name of M. Chydenius, Professor at Helsingfors (Finland), a note on "*Euxenite*." The author has demonstrated the presence of thorina in this mineral.

November 16, 1866.

M. Berthelot *in the chair.*

M. Gal gave an abstract of his researches on organic ethers.

MM. Friedel and Ladenburg stated that they had attempted to prepare a hydrocarbon having an analogous constitution to that of silicium-ethyl. Methyl-chloracetol, a derivative of acetone, reacting on zinc-ethyl at a mode-

* See Du Moncel sur l'Electricité, 1862, page 248.

rate temperature, produced a hydrocarbon, C_7H_{16}, isomeric with several other hydrocarbons already known.

M. Berthelot described the several hydrocarbons he had succeeded in obtaining by heating them 2 by 2, 3 by 3, &c.

M. Debray announced the production of several salts of alumina obtained by the action of zinc on neutral sulphate of alumina, or of chalk on alum. He had in this manner prepared a crystallised neutral nitrate of alumina having an analogous composition to that of nitrate of the peroxide of iron.

NOTICES OF BOOKS.

Watts' Dictionary of Chemistry. Part XXXVII. January, 1867. London: Longmans, Green, Reader, and Dyer.

We have already given full notices of the earlier parts of this valuable and standard book, and have to remark now that the present number yields to no former one in the interest of its contents.

We can do our readers a good service by quoting from the present part the following article as a type of the amount of the latest researches contained in its pages:—

"*Sodammonium*, NH_3Na, or, rather, $N_2H_6Na_2$(?) (Weyl, *Pogg. Ann.*, cxxi. 697; *Jahresb.*, 1864, p. 163). This compound appears to be formed when lumps of pure bright sodium are placed at one end of a bent tube, a quantity of silver chloride previously saturated with ammonia gas at the other; the tube is then sealed, the end containing the silver chloride heated in a chloride of calcium bath, and the other end immersed in cold water. The sodium then swells up, and is converted into a liquid which is copper-red by perpendicularly reflected, greenish-yellow by obliquely reflected, light, blue in thin films by transmitted light. As the silver chloride cools, and the ammonia gas is reabsorbed, the sodammonium decomposes, and pure sodium remains behind, having a dull surface and spongy texture. By again heating the silver chloride, the compound may be reproduced any number of times. A sodammonium amalgam appears to be formed by exposing in like manner to the action of ammonia gas a pulverulent amalgam of nearly equal parts of sodium and mercury. After two hours' action, the portion of the mass in contact with the surface of the tube exhibits a metallic lustre and a bronze-red colour, while the interior is dull and brick-red. This product can likewise exist only in an atmosphere of ammonia, being resolved, in a few hours after the cooling of the silver chloride, into ammonia, free mercury, and a sodium amalgam containing less mercury than the original amalgam.

"*Potassammonium*, $N_2H_6K_2$(?), is prepared like sodammonium, and exhibits similar properties. Other metallammoniums may be produced by the decomposition of sodium or potassammonium. Thus, when a mixture of a metallic chloride or oxide with an equivalent quantity of sodium is exposed in the manner above described to the action of ammonia gas, the gas is first absorbed by the metallic chloride (or oxide), and afterwards by the sodium, the sodammonium thus formed flowing over the metallic salt, and reacting upon it without much rise of temperature. With a mixture of barium chloride and sodium the reaction seems to be—

$$\underset{\text{Sodammonium.}}{N_2H_6Na(qy.\,Na_2?)} + 2NH_3 + Ba''Cl_2 = \underset{\text{Barammonium.}}{N_2H_6Ba''} + 2\underset{\text{Chloride of sodammonium.}}{NH_3NACl}$$

"Barammonium forms a deep blue liquid having a metallic lustre. Copper, mercury, and silver ammonium are obtained in like manner from their respective chlorides, and zinc ammonium from the oxide. These compounds are likewise very unstable, being resolved, even in the sealed tube, into metal (which appears grey, dull, and destitute of coherence) and ammonia. If in the arrangement just described the metallic chloride be replaced by an ammonium salt—*e. g.*, NH_4Cl or $(NH_4)_2SO_4$, similar reactions take place, and the tube becomes filled with a blue liquid, mixed with excess of ammonia. This blue liquid, which is also formed by the action of potassic hydrate on potass-ammonium, appears to consist of *ammonium itself*, N_2H_8. It is even more unstable than the metallammoniums, being resolved into ammonia and hydrogen, partly even before the reaction between the ammonium salt and the sodammonium is completed.

"*Tetrasodammonium*, NNa_4 (?).—Monosulphide of sodium brought in contact, in a sealed tube, with liquid ammonia, is converted (with transient formation of liquid ammonium) into an orange-yellow substance, which soon decomposes, leaving a white substance still containing ammonia. This residue gives off ammonia on exposure to the air, and the odour of ammonium sulphide when heated. It is perhaps formed in the manner represented by the equation—

$$4Na_2S + 8NH_3 = (NNa_4)_2S + 3(NH_4)_2S.$$

"*Tetrapotassammonium* appears to be formed in a similar manner. (Weyl)."

The concise form of the information, great in amount, contained in one short article, will serve to show the character of the others, without our alluding to them more fully. We may state that in this part of ninety-six pages are contained full details of what is known respecting sodium, silicon, and silver among the elements, many vegetable principles, and names of the chief minerals in which the preceding elements are found.

The essay on silver assaying is perfect in its clearness and comprehensiveness, and is decidedly *the* article of the present part. But it almost seems as if the information and authorities quoted are not given so fully as they were in the earliest parts, as if it were feared that the quantity of matter yet remaining required curtailing for the whole work to occupy the arranged limits.

In other words, must the matter be crammed in to occupy a given number of volumes, or must the number of volumes be increased to allow justice to the work?

We would urge, on the behalf of the readers of the Chemical News, an extension of the original scheme by another volume, or, if needs be, two more. The work is, indeed, a classical one, and well worthy all the pains bestowed upon it by its talented editor, and we hope that neither the authors, publishers, nor chemical readers generally will fail in their respective duties in completing a work, at present and thus far, without a rival. Our interest in the Dictionary is too deep to prevent our feeling an anxiety on its account. We hope, therefore, that the additions, which must be proportionate with the progress of modern chemistry, will not be interfered with by preconceived limits. We further hope that appendices will also be published, embracing discoveries and views only lately made known, bearing upon the subjects of the earlier articles. The publishers, by so enlarging their scheme, will well earn the thanks of the profession at large, and we feel sure that they will be fully encouraged by those who have appreciated and done justice to the merits of "Watts' Dictionary of Chemistry."

The Modern Practice of Photography. By R. W. Thomas, F.C.S. London: Harrison. 1866.

In this little manual the author confines himself exclusively to the one process in photography which he considers the best—viz., the production of negatives with wet collodion, and printing upon albuminised paper. This process is fully gone into, and every point of difficulty carefully explained, particular stress being laid upon those operations in which beginners are principally liable to fail, and which are absolutely necessary for the production of

perfect pictures. Thus, a chapter is devoted to instructions for cleaning the plates, and another for varnishing the negatives, both of them subjects to which the young photographer at first seldom attaches due importance. The relative merits of iodised and bromo-iodised collodions, iron and pyrogallic acid developments, &c., are carefully stated, while the formula for the nitrate bath insures the maximum sensitiveness, together with the entire absence of any injurious or unnecessary matter.

For those photographers who are willing to thoroughly master one process before yielding to the allurements of tannin, albumen, &c., this manual will be found all that can be desired.

CONTEMPORARY SCIENTIFIC PRESS.

[Under this heading it is intended to give the titles of all the chemical papers which are published in the principal scientific periodicals of the Continent. Articles which are merely reprints or abstracts of papers already noticed will be omitted. Abstracts of the more important papers here announced will appear in future numbers of the Chemical News.]

Deutsche Industrie Zeitung. 1867. No. 4.

Rosenstiel "*On Lucine*—i.e., *Dried Gluten—as a Substitute for White of Eggs in Calico Printing.*"—J. Bremen "*On Engraving on Marble by means of Chemicals as a Substitute for Carving.*"—Reinsch "*On the Occurrence of Phosphoric Acid in Coals.*"

Journal für Gasbeleuchtung. 1867. No. 1.

Dr. Schilling "*On the Varying Quantity of Sulphuretted Hydrogen met with in Crude Coal Gas, obtained from divers varieties of Coal, and on the Quantitative Estimation thereof; with Description of an Apparatus to obtain these Results readily and rapidly.*"—L. Rambohr "*On Kreosote Gas and the valuable By-products obtained in its Manufacture.*"

Le Moniteur Scientifique. Nos. 241 and 242. 1867.

Rignon "*On quick Soap-making.*"—Brissé "*On the Nutritive Quality of divers varieties of Cheese.*"

Polytechnisches Centralblatt. 1866. No. 24.

Wyrouboff "*On the Colouring Matters met with in Fluor Spar.*"—Knapp "*On Matches without Phosphorus*"—viz., 3 parts of sulphuret of antimony, 16 chlorate of potassa, 1 bichromate of potassa, 10 red lead, 8 nitromannite, 4 glass, 5 gum.—Dr. Vohl: "*Results of Analysis of Crude Boracic Acid from Tuscany.*"—J. Kolb "*On the Density of Nitric Acid, with a Table.*"—Dr. Fleckner: "*Analysis of Bauxite from Feistrisz, in Carynthia.*"—Dr. Bolley "*On a Yellow Dye Stuff obtainable from Indigo in Crystallised State*"—*i.e.*, naturally occurring in indigo.

Le Technologiste. No. 325.

Henri Mares "*On the Influence of Heat on some varieties of Languedoc Wines.*"—C. Randtl "*On the Pressure which the Carbonic Acid, developed from Beer while in Fermentation and kept in Closed Casks, exerts upon the Process of Fermentation.*"

No. 326.—"*On the Varieties of Coloration of Brass.*"—Griess "*On Aniline Yellow.*"—Hauch "*On a Simple Process to Prepare from Crude*—i.e., *Native—Sulphur Flowers of Sulphur.*"—Violette "*On Resins.*"

No. 327.—Vysoky "*On the Manufacture of Uranium Yellow at Joachimsthal, in Bohemia.*"—Gerlach "*On the Specific Gravity of Solutions of Sulphate of Iron and Sulphate of Copper.*"—Grundmann "*On the Loss Mineral Fuel, especially Coal, Suffers in its Quality as Good Fuel by being Exposed to Air.*"

No. 328.—Fischer: *Researches on the Purple of Cassius.*"—Dr. Vohl "*On the Extraction of Fixed Fatty Oils from Seeds by means of Paraffin and other similar kinds of Oils.*"—Senefelder "*On Indelible Ink.*"—"*On the Explosive Force of Sodium.*" 30 grammes of sodium brought into contact with water explode with equal force as 9 kilogrammes of gunpowder, or 9 hectogrammes of nitroglycerine. 600 grammes of sodium in contact with a spoonful of water will do the same effect as 1800 kilogrammes (nearly two tons) of gunpowder.

NOTICES OF PATENTS.

Communicated by Mr. Vaughan, F.C.S., Patent Agent, 54, Chancery Lane, W. C.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

64. L. Hand, Coleman Street, London, "Improvements in treating benzole and other hydrocarbon liquids, and in making such liquids non-explosive, and of generating an illuminating gas therefrom." A communication from J. Johnson, Wilmington, Illinois, U.S.A.—Petition recorded January 10, 1867.

73. F. J. Evans, Westminster, "Improvements in the manufacture of illuminating gas."—January 11, 1867.

87. W. G. Blagden, Hackney Wick, Middlesex, "An improved method of separating silver from lead." A communication from F. Marquez-Millan, Rue Liandier, Marseilles, France.—January 14, 1867.

119. E. Süvern, Halle, Prussia, "An improved mode of and apparatus for purifying the impure waters emanating from sugar factories and other industrial establishments, applicable also to the purification of sewage water."—January 17, 1867.

128. B. Lietar, Rue du Houblon, Brussels, "An improved composition to be employed in welding or soldering iron upon iron, steel upon steel, and iron upon steel."

130. D. W. Hamper, Newcastle-on-Tyne, "Improvements in the preparation of finings for fining or clearing fermented liquors."

131. J. G. Franklin, Broadway, Somersetshire, "Improvements in tanning."

134. W. Weldon, West Hill, Highgate, Middlesex, "An improved method of manufacturing chlorine."—January 18, 1867.

148. G. L. Loversidge, Greenfield, Saddleworth, Yorkshire, "Improvements in the tanning of hides and skins, and in the apparatus employed therein."

152. J. Rowley, Grosvenor Terrace, Camberwell, Surrey, "An improved process for hardening, bleaching, and sweetening crude paraffin."—January 21, 1867.

164. J. Patison, Airdrie, Lanarkshire, N.B, "Improvements in the production of illuminating gas, and in the manufacture and application or use of new or improved materials or fuels for the same, and in the means or apparatus employed therefor."—January 22, 1866.

172. H. A. Bonneville, Rue du Mont Thabor, Paris, "A new or improved process of treating skins, in order to separate therefrom the hair and wool, and in the preparation of the hair for the manufacture of hats." A communication from A. Frayssé, jun., Rue Croix-des-Petits-Champs, Paris.—January 23, 1867.

211. J. J. Lundy, Leith, Midlothian, N.B., "Improvements in the treatment of the residual matters resulting from and obtained in the purification and distillation of mineral or hydrocarbon oils, and also in the treatment of coal tar and various waste or other alkaline and lime substances for the purpose of utilising the same."—January 26, 1867.

Notices to Proceed.

2460. W. Cormack, Commercial Road, Middlesex, "Improvements in means and apparatus for effecting the revivification of animal charcoal."

2472. J. J. Lundy, Leith, Midlothian, N.B., "Improvements in the treatment of the residues resulting from and obtained in the purification and distillation of mineral oils, for the purpose of utilising the same."—Petitions recorded September 25, 1866.

2478. T. Amey, Petersfield, Hampshire, "An improved process for preserving milk, and apparatus connected therewith."

2479. J. C. Sellars, Birkenhead, Cheshire, "A new and improved metal founders' blacking, and mode of treating or preparing the same."—September 26, 1866.

2534. D. Barker, Northfleet, Kent, "Improvements in the manufacture of artificial fuel."

2645. E. Beanes, Priory Road, Kilburn, Middlesex, "Improvements in refining or decolorising sugar and syrup."—October 12, 1866.

2733. J. Greenshields, Glasgow, N.B., "Improvements in making gas and coke."—October 23, 1866.

CORRESPONDENCE.

Organic Matter in Water.

To the Editor of the Chemical News.

Sir,—"Silence" is said to give "consent," but I cannot suppose that Dr. Letheby wishes us to think that he consents to your correspondent, "Thomas P. Blunt, B.A., F.C.S." (*vide* Chemical News of Jan. 25), taking up the office of exponent of his views on water analysis, although he has treated the latter's letter with the same expressive silence that he employed towards mine.

Mr. Blunt flatters himself that his letter discloses a "method" which is "no doubt substantially identical with that in use by Dr. Letheby." This "method," he admits, is perhaps "not theoretically perfect," and, as Dr. Letheby has not offered to enlighten him, I may, perhaps, be allowed to point out to the latter that its "practical value" will appear rather diminished if he will be good enough to answer the following queries:—1. If a fresh solution of some nitrogenised organic matter of animal origin (*e.g.* albumen) were sent to Mr. Blunt for analysis, would he, because he detected no ammonia or nitric acid in the solution, return a report that "it contained no organic matter of animal origin?" 2. Does Mr. Blunt know that nitrogenised organic matter (say for instance, as before, albumen) has been found to form part of the constitution of vegetables? 3. Would he therefore, should a solution of such organic matter be sent to him for analysis, after the nitrogenised matter had been decomposed into ammonia and nitric acid, conclude and report that "the organic matter was entirely of animal origin?" 4. If Mr. Blunt should fail to detect ammonia or nitric acid in a sample of Thames water, would he conclude that the inhabitants of the towns above the point where the sample was collected had kindly omitted to pour any nitrogenised organic matter of animal origin into it that day—say, for instance, sewage, an occasional constituent of that river which Dr. Letheby pronounces to be "free from organic matter of animal origin?" 5. What "practical value" ("perfection in theory" seems to be considered by Mr. Blunt as of little importance) would conclusions such as I have described have?

Not content with explaining what he conceives to be Dr. Letheby's "method" of detecting "animal organic matter," Mr. Blunt calls our attention to the "beautiful system" by which the former expresses the "oxidisable organic matter" in water in terms of oxalic acid. The "theoretical perfection" of this "beautiful system" will be apparent to your readers when they reflect that Dr. Letheby seems to consider that his deep acquaintance with the "oxidisable organic matter" in water warrants him in selecting oxalic acid (not because of its being so certainly acted upon by permanganate of potash, or because it can be obtained very pure, but) because it is the best type of such organic matter we possess. They can also form some idea of its "practical value" when I tell them that the city analyst of Dublin, in a recent report, informs the public that he considers this typical place to be held by sugar. I need not ask Mr. Blunt whether permanganate of potash acts on oxalic acid and on sugar in the same degree. I am, &c.

B. J. G.

Standard Thermometers.

To the Editor of the Chemical News.

Sir,—As the question touched upon by your correspondent, "Zero," about standard thermometers is of considerable importance on account of the comparison of accurate thermometric observations—as, for example, those suggested by Drs. Compton and Aitkins for the careful observations of the temperature of the human body during disease—I venture a few words on the point.

In your article it is stated that Mr. H. C. Kay's instrument, as certified by Mr. Glaisher, differs 1½° from the instrument with a Kew certificate. This statement implies at once that there are either two standards in England, that of Kew and that of Greenwich, differing 1½° from each other, or that Mr. Glaisher must have made a mistake of 1½° by the comparison of this instrument. Now neither of these suppositions is probable, for it is not likely that the standards at Kew and Greenwich should differ to any measurable unknown amount, nor is it likely that a man like Mr. Glaisher would make such a mistake. It is, therefore, evident that we must otherwise account for this difference. I applied to Mr. F. Pastorelli, of 208, Piccadilly, one of the most careful and accurate manufacturers, for an explanation, which he was kind enough to give me at once. Mr. Pastorelli informed me that it was a fact, known to most practical and accurate manufacturers, that thermometers made in the usual way did acquire gradually an increasing index error which would reach the maximum of 1 to 2 degrees about a year after the manufacture, but remain then as good as constant. Mr. Pastorelli believes this increasing error to be owing to the contraction of the glass after its manufacture. He explained to me a process he followed to avoid this after-contraction as much as possible, but this I shall pass over as being merely important to manufacturers.

After the above explanation it is, therefore, very probable that Mr. Kay's instrument acquired this greater additional index error first after its comparison by Mr. Glaisher with the standard. But how have we to account for it that the instruments with the Kew certificates should not have acquired the same increased error? This may be that those instruments were originally more carefully made, or adjusted some time after their manufacture. But if such considerable errors are possible even in certified thermometers, it would perhaps be advisable to place at different easily accessible localities standard instruments which are carefully rectified, to enable any gentleman engaged in meteorological, medical, chemical, or other thermometric observations, to convince himself of the correctness of his instrument, so that an accurate comparison of different observers can easily be made. I am, &c.

A Subscriber.

Commercial Analyses.

To the Editor of the Chemical News.

Sir,—An instance illustrating the want of a proper understanding on all hands has lately come under my notice. Chemist A, or Professor B.—no matter which—receives a sample of artificial manure, with a request that he will give a determination of the nitrogen contained. The analysis is performed and the fee paid; we will suppose it was one guinea, or, if under a contract for a considerable number, it may be half a guinea each all round. The amount of nitrogen is small, not more than an ordinary superphosphate generally contains, say 0·27. A dispute arises between the manufacturer and his customer, who may be a member of a farmers' club; an investigation follows, and in the course of a week or two, or it may be more, during which the poor manufacturer loses his trade among the members of the club, the secret is told. The chemist has

only tested by lime- and soda-combustion for ammonia from organic sources, or salts of ammonia, nitrate of soda being entirely overlooked, because the process is troublesome and the fee small. The manure in question is now found to contain 12 per cent. of nitrate of soda, or about 2 per cent. more nitrogen than the chemist or professor had reported. But now it is the chemist's turn to be on his trial, and his plea is that the fee is inadequate for the work required. Granted by all means. But if so, why undertake it? You go to your solicitor, and give him instructions to draw a will, a lease, or a settlement, it may be, for one of Professor B's daughters; you ask the cost; the price is agreed. Ten years hence your will is found to be bad and invalid, your lease full of omissions, or Professor B.'s daughter loses all her fortune through the bungling of the solicitor. Now, what solicitor in his senses would plead, as an excuse, that the fee was too small? or who would not call him a rogue for undertaking the work at all, well knowing that his client was only throwing away his money?

While we have chemists so devoid of proper professional feeling that they will work for almost any fee, of course the public will employ them. But even if chemists like to work *gratis*, I submit they are bound to do their work properly or not at all. I am, &c.

COMMON-SENSE.

Sudden Irruptions of Fire-damp in Mines.

To the Editor of the CHEMICAL NEWS.

SIR,—In your notice on the 11th ult. of Mr. Ansell's very ingenious fire-damp indicator for coal mines, you speak of sudden irruptions of fire-damp to such an extent as to render the air of even a mile of space explosive in a few minutes. I presume this means a mile in length of air-course, not a square mile of mine excavation; but is this circuit even of a mile in length, say 5000 feet of air-course of, say, 10 feet wide by 5 feet high, 50 square feet —*i.e.*, 250,000 cubic feet of safe air—rendered explosive "in a few minutes?" Of course that is quite possible, if the air is at first only just non-explosive; but is it true that so large a bulk of air giving no indication of fire-damp does become explosive in a few minutes from the sudden evolution of gas from the coal? Of course it may, if there be a large collection of gas in a goaf or other abandoned or neglected workings disturbed by an extensive fall of roof, or by powder blasting or expanding into the workings by sudden and great fall of the barometer; but that there should be a sudden increase of gas produced, beyond the usual power of the ventilation to dilute, of some 20,000 or 25,000 cubic feet direct from the coal in a few minutes is contrary to the usual opinion of miners, and seems very improbable. It is a very common opinion that if no indications of the presence of fire-damp be discoverable in the morning, there is no risk of any large explosion extending throughout the mine during that day, if the ventilation then found sufficient be maintained. It is allowed that small local explosions may nevertheless occur from local increase of gas evolved by blowers appearing or increasing, but that a large general explosion is next to impossible, from the great improbability of a great number of blowers suddenly increasing their discharge at the same time, unless, indeed, there be a great fall of the barometer, which rarely occurs during a few minutes. It is very important that this point should be settled, for many persons contend that the simple occurrence of a *large* explosion all but absolutely proves either that there must have been a very considerable accumulation of gas in the mine for some hours, perhaps days, previously, or that the ventilation of the part exploded had been considerably diminished. I believe one of these would be generally the correct conclusion; but, if it be not so, mine managers are likely to be accused of negligence when they have not been really guilty, and the absolute necessity for some much more immediate indication of danger than is now in use will be established. My hope and expectation is, that Mr. Ansell's indicator will supply this great and urgent want, and that by its means the master's eye will in effect always be present in the depths of the mine, keeping those alert on whose never-ceasing care the ventilation, and with it the safety of hundreds, depends. I am, &c.

P. H. HOLLAND.

London, February 6.

MISCELLANEOUS.

"**Buckmaster's Physiology.**"—In our notice of this book a few weeks ago we invited an explanation of the strange title of the book, Mr. Angel being the author. Mr. Angel has sent us a long answer to the inquiry, and we regret that we have not the space to give it *in extenso*. He tells us that he knew that the work would be published in Buckmaster's series, but quite expected that "his name would be published as the author in the same way as that of Dr. Carpenter or Dr. Wilson in Bohn's or Chambers's series," and was himself disappointed by the manner in which the work was bound up. We see no reason why the publisher should not, thus late, satisfy Mr. Angel's natural wish that no doubt should be left as regards the authorship.

Meetings for the Week.

Tuesday, February 26.

Royal Institution, 3 p.m. Professor Tyndall, F.R.S., "*On Vibratory Motion and Sound.*"

Royal Medical and Chirurgical, 8½ p.m.

Wednesday, February 27.

Society of Arts, 8 p.m.

Thursday, February 28.

Royal Institution, 3 p.m. Professor Tyndall, "*On Vibratory Motion and Sound.*"

Royal Society, 8½ p.m.

Friday, March 1.

Royal Institution, at 8 p.m. Captain V. J. Majendie, "*On Breech-loading Small Arms.*"

Saturday, March 2.

Royal Institution, at 3 p.m. G. A. Macfarren, Esq., "*On Harmony.*"

ANSWERS TO CORRESPONDENTS.

Assayer, Chemicus (Liverpool), and others, next week.

Dr. F.—A process such as you describe would be of great value, but we do not consider that you have solved the difficulty.

Therma.—Breguet's metallic thermometer will be the best for your purpose. Siemens' electric resistance thermometer would be unsuitable.

George T.—Arsenic and tin in solution may be separated by converting them into sulphides, and dissolving the sulphide of arsenic in bisulphite of potash. Sulphide of tin is insoluble in this.

A. S. L.—Probably you mean benoleic acid, a derivative of bromerucic acid. It was discovered by Hausknecht. We never heard of benoteic acid.

Prussian Blue.—"Chromium" inquires for a likely market for a good and cheap Prussian blue pigment, which he has facilities for making.

Spirit of Nitrous Ether.—In our report of Professor Redwood's paper given in our last number, page 79, in speaking of the 1864 process, *nitrate* of potash was mentioned as possessing the indefinite composition complained of. Our readers will perceive at once that this is a clerical error, nitrite of potash being meant.

Child.—Putrefaction or decomposition will not *produce* animal life in the sense you mean; but the germs of life being present, their development is frequently the cause of putrefaction, whilst sometimes their development is hastened by the decay of body in which they find themselves.

A Confectioner.—Essence of apricot is made by mixing 1 part of chloroform, 10 parts of butyrate of ethyl, 5 parts of valerianate of ethyl, 1 part of œnanthylate of ethyl, 2 parts of salicylate of methyl, 1 part of butyrate of amyl, 1 part of cold saturated solution of tartaric acid in alcohol, and 4 parts of glycerin. The whole to be dissolved in 800 parts of alcohol.

Titration of Ethers.—A Subscriber writes:—"I was not present at the meeting of the Chemical Society at which Prof. Wanklyn brought forward the above subject. I now beg to express my regret for having thus, unwittingly, done injustice to Prof. Wanklyn's knowledge of chemical literature."

IRRUPTIONS OF FIRE-DAMP IN COAL MINES.

In a notice of Mr. Ansell's ingenious indicator given a few weeks ago, we spoke of sudden irruptions of fire-damp to such an extent as to render the air of even a mile in extent explosive in a few minutes. There are very many recorded cases of sudden irruptions of fire-damp in such quantities as to far surpass the amount quoted in our recent article; but as Mr. Holland, in our last number, raised the question, and appeared to consider that such cases, even if occurring, were at all events very exceptional, we propose to give the subject a greater consideration. We quote from a paper written by Mr. John Brown—who is admittedly the most trustworthy mining engineer in South Yorkshire—and we think that the following cases are in point as regards Mr. Holland's communication. Speaking of an explosion which occurred at the Shipley Colliery in 1851, he says:—"It was known that the coal and the strata in connexion with it yielded fire-damp; but no great quantity had manifested itself until August 8, 1851, when an explosion took place in the evening, whereby several persons were burned, &c. . . . . In a few minutes afterwards this was followed by an explosion at the furnace." Upon examination it was discovered that the floor in one of the stalls "had been violently upheaved; one side of the tramway which crosses the face of the workings being raised nearly two feet higher than the other, and fire-damp was issuing in large quantities from the fissures. It being night, the gas had passed till it came in contact with a candle. After exploding here, a sufficient quantity passed to the furnace to produce a second explosion." After detailing two other sudden irruptions, the writer goes on to express an opinion "that no amount of ventilation that could be produced in that mine would prevent an explosion either at a naked light or at the furnace, or at both.

Again, in speaking of the Oaks Colliery at Barnsley, he says:—"In January, 1857, a large quantity of gas was given off suddenly in the dip works;" he thinks from the roof. He continues:—"The men in this district immediately retired, their lamps being extinguished. No person was working near the upcast pit, so I am unable to state in what condition the return air was when it arrived at the pit; but it must have been very much charged with fire-damp." Again: "In August of the same year a very much larger issue of gas took place in a bank in the dip workings, coming off from the floor, which was much heaved up and broken. The noise made by the gas rushing violently was quite alarming. From the point of issue, which was in the bank nearest to the intake, to where the last man was working was about 400 yards; and along this line part of the men were working with Stephenson's and the remainder with Davy's. The whole of the former were extinguished, and the latter became red-hot before the wicks could be drawn down, but most fortunately they were put out without an accident." "There can be no doubt," says Mr. Brown, "that if the return air had passed over a furnace, an accident of a frightful character must have happened." Once more: speaking of the Oaks Colliery in September, 1858, the author from whom we have so freely quoted says:—"Early in the morning the man whose duty it was to examine the pit prior to the colliers going to work, discovered that a fall of roof had taken place on the south side of the pit. The gas continued to come off rapidly for four or five hours. I made some calculations at the time which convinced me that *at least* as much pure fire-damp came off that morning as would have filled a heading six feet square and a mile and a half long; probably there was much more than this."

Such an amount of *pure* fire-damp diluted to the explosion point would in twenty minutes or less render a mile perfectly explosive, but, as a more recent case, Mr. Ansell has recorded that he was present in a pit when an enormous amount of gas suddenly issued, having been released by blowing out a block of coal which stood square and up to his waist—he believed considerably more than a ton—and, at a distance exceeding 400 yards, heard this gas roaring in such a manner as to cause alarm; upon reaching the spot, he found that the gas was issuing from a funnel-shaped opening, into which he thrust his arm up to the shoulder. It is admitted on all hands that the gas issues from great reservoirs under considerable pressure, but Mr. Ansell seems to have satisfied himself that it exists in a liquid state, and he has seen cavities in which he thinks it is more than probable the liquid was retained.

TECHNICAL CHEMISTRY.

*The Theory and Working of Blast Furnaces, by Wm. Crossley, F.C.S., Manager Ormesby Iron Works.**

Perhaps no part of "furnace chemistry" is so little understood as that connected with the manufacture of iron in a blast furnace, and yet experience and frequent experiment have gradually improved the appliances and construction of blast furnaces, and shown the conditions under which they work most favourably, until at the present time I do not know of any other manufacture that is carried out on such a systematic and gigantic scale, nor one which promises at no distant period to be more thoroughly understood. Of course, in some of the older districts, and especially with those firms who have long had a name for the quality of the "pig" or "merchant" iron they produce, and a demand which places them above competition, the appliances and the process of manufacture are very primitive; but in the modern districts, and especially in Cleveland, every advantage is taken of all the discoveries and appliances that seem at all likely to answer the purpose for which they are intended; and the enterprising spirit shown by the ironmaster in the erection of improved plants and the alteration of old plants, to decrease the cost, improve the quality, and increase the make of iron, is worthy of all commendation.

I purpose in the present communication to point out some of the improvements that have been made, give some explanation of their effect, and, if possible, show in what direction any further efforts we may make ought to tend.

* Communicated by the author.

In a blast furnace the fuel and the material on which it has to act when undergoing the process of combustion are introduced together at the top of the furnace, and it takes from twenty-four in some of the older furnaces, to forty-four or even fifty hours in those most recently built, before it reaches the "crucible" part or the hearth, where combustion is going on, the cast iron formed and melted, and the slag allowed to escape. To assist ourselves in fully understanding the subject, it will perhaps be the best plan to follow the material in the changes it undergoes from its introduction at the top to its elimination as slag and iron at the bottom.

In an ordinary-sized furnace the material will be introduced about forty feet from the point of combustion or the tuyeres,† and hence it will be very gradually raised from the temperature at which it comes from the calcining kilns to the highest temperature of the furnace, and it is probable that the largest pieces of ironstone or limestone will be of nearly the same uniform temperature when they reach the point where limestone and ironstone act on each other, and combine to produce slag.

The first effect due to the hot gases produced by combustion passing through the furnace will be to raise the temperature of the material through which it passes up to that point where limestone is decomposed into carbonic acid and quicklime (and when the evolution of gases commences it is likely that the temperature will not increase as quickly as before this point is reached, owing to the liberated gases removing a portion of the heat of the furnace with them); at this point, too, any volatile or organic matter left in the stone by imperfect calcination will be driven off. It is probable, too, that near this place the peroxide of iron in the iron ore is sufficiently heated for the carbonic oxide to act upon it and reduce it to the metallic state, and this action will continue until at last all the iron will be distributed through the stone in the metallic form. The intensely heated material now travels on, the intensity of heat increasing as it approaches the "hearth" until at last the "melting region" is reached, where the earthy matter in the ironstone melts, and, acting on the limestone, the production of slag follows; a little below this the reduced iron will also melt, and at the same time probably combine with a portion of the carbon of the coke; nearer to the tuyeres still, some or all of this combined carbon may be resolved into the "graphitic" form, traces of silica, lime, &c., reduced and alloyed with the iron, and cast iron result.

We will now in like manner attempt to follow the blast in at the tuyeres, and to explain the changes it takes part in before finally leaving the furnace as "furnace gas."

The blast will probably first combine with the carbon of the coke, and produce carbonic acid; this will heat another portion of the coke sufficiently to enable it to reduce the carbonic acid to carbonic oxide ($CO_2 + C$ becomes $2CO$), and this intensely heated carbonic oxide will ascend in the furnace, gradually cooling as it ascends, owing to abstraction of heat by the material through which it passes. Higher in the furnace the carbonic oxide meets with unreduced oxide of iron, from which it abstracts the oxygen, producing an equivalent of carbonic acid; this carbonic acid is thought by some to be wholly or partially reduced again to carbonic oxide. For reasons which will be stated immediately, I have some doubt about this being the case, but certainly the greater part of the oxygen introduced in the blast leaves the furnace combined with carbon as carbonic oxide. This, of course, is mixed with the nitrogen of the atmosphere, the carbonic acid from the limestone, and the volatile matter not driven off during the process of calcination.

It is hoped that ultimately the analysis of furnace gas may lead to a better knowledge of the changes which take place in a blast furnace in the reduction and smelting of cast iron, but those already published are extremely unsatisfactory in some respects, either from the bad choice of furnace from which the gas analysed has been collected, or from the fact that there have been so many interfering circumstances at the time that it is difficult to draw any reliable conclusions from the results obtained. I have devoted a great deal of time to the examination of the analysis made by Ebelmen at Clerval and Audincourt in France, and at Seraing in Belgium; by Bunsen and Playfair at the Alfreton furnaces, England; by Bunsen, at Veckerhagen; and, lastly, by Scheerer and Langberg at Baerum, in Norway. I found it impossible from the reasons named to gain any information of value, with perhaps one exception—viz., in the case of the analysis of gas from a furnace at Clerval in France, by Ebelmen, a French chemist, which analysis seems to point to the fact that there is not that constant series of changes from carbonic oxide to carbonic acid, and from carbonic acid to the oxide, which has always been supposed to be the case, but that all the carbonic acid produced by the oxygen of the iron ore combining with the carbonic oxide leaves the furnace as carbonic acid, and is not again reduced to carbonic oxide—in other words, that the temperature at which oxide of iron can be reduced by carbonic oxide is below that at which carbon can remove an equivalent of oxygen from carbonic acid.

(To be continued.)

† In some of the larger furnaces the material is introduced seventy feet from the tuyeres, and in two furnaces recently built by Messrs. Bolckow and Vaughan, at Eston, the height of the furnaces has been increased to ninety-six feet.

On a New Process of Organic Elementary Analysis for Substances containing Chlorine, by C. M. Warren.

(*Concluded from page 74*)

III. *Experiments with Oxide of Zinc, as an Absorbent of Chlorine in the Analysis of Substances Rich in Hydrogen.*

In these experiments, the oxide of zinc was employed in the same manner as above described for the analysis of chloroform. The chloride of amyl, which was the subject of analysis, was prepared in the usual manner. Its boiling point was 102°, 8 corrected.

The following results of two analyses with oxide of zinc indicate that this oxide combined with and retained some of the carbonic acid. This result was not anticipated, as in the analysis of chloroform the determination of carbon was uniformly slightly in excess.*

* Since the above was written, I have observed, on reviewing my notes—not only of experiments with oxide of zinc, but also with oxide of copper—that in every analysis in which I made note of carbonisation, or blackening of the asbestos in the combustion tube—which may sometimes occur from too rapid distillation of the substance, or, what amounts to the same thing, a deficiency in the supply of oxygen—there was a loss in the determination of the carbon, and generally, also, in that of the chlorine; while the hydrogen would agree pretty nearly with the theoretical quantity. I am, therefore, at the present writing inclined to suspect that the carbonisation may have had some connexion with the deficiency in the carbon determinations in these instances, although the blackening would readily and completely disappear so soon as a sufficiency of oxygen was supplied. This momentary blackening of the asbestos occurred in both of the analyses of chloride of amyl with oxide of zinc, but, as already intimated, was not regarded at the time of serious consequence, as similar phenomena in the analysis of hydrocarbons by my process were generally attended with good results. It may, therefore, remain an open question, whether the oxide of zinc may not serve a good purpose in the analysis of substances of the class now under consideration.

The results of these two analyses are as follows :—

1.—0·1922 gramme of chloride of amyl gave 0·3513 of carbonic acid, 0·1854 of water, and 0·2528 of chloride of silver.

		Calculated.		Found.
Carbon .	C_{10}	60	56·3910	49·85
Hydrogen .	H_{11}	11	10·3383	10·72
Chlorine .	Cl	35·4	33·2707	32·47
			100·0000	93·04

2.—0·1657 gramme of chloride of amyl gave 0·3314 of carbonic acid and 0·1608 of water.

		Calculated.		Found.
Carbon .	C_{10}	60	56·3910	54·56
Hydrogen .	H_{11}	11	10·3383	10·74
Chlorine .	Cl	35·4	33·2707	

IV. *Experiments with Oxide of Copper, as absorbent of Chlorine in the Analysis of Substances Rich in Hydrogen.*

In these experiments, for the reason previously stated, the oxide of copper could only be placed in the anterior end of the combustion tube, where it might be maintained at a tolerably low temperature. After two or three experiments—which were but partially successful—it became apparent that the range of temperature within which oxide of copper could be made serviceable to absorb the chlorine was probably rather limited.

It was observed, for example, that at 150° to 160° even brown oxide of copper, which had been but gently ignited, would fail to absorb nearly all of the chlorine, and consequently the determination of the carbon, and sometimes that of the hydrogen, would be in excess. In one experiment, in which the oxide of copper was kept at about 153° C., its appearance had suffered no change, and it was found to contain only 8·29 per cent. of chlorine, or only about one quarter of the theoretical quantity. When a sufficiently high temperature is employed, on the contrary, the posterior end of the column of oxide of copper and asbestos has the appearance of being entirely changed into yellow chloride of copper, the rest of the column remaining, for the most part, of its original dark colour.

In another experiment, with the oxide of copper kept at a temperature of about 160°, only about 14 per cent. of chlorine was obtained.

In both of these experiments the carbon determination was considerably in excess, and in one of them the hydrogen also. The oxide of copper employed had been strongly ignited.

Before proceeding further with these somewhat random experiments, it was deemed advisable to determine the temperature at which chloride of copper begins to give off chlorine, in order to know how far it would be safe to raise the temperature of the air-bath in conducting an analysis. By making use of the air-bath to regulate the temperature of the chloride of copper, this determination was easily made. During the heating of the chloride, a current of air from the air gasometer was admitted through the tube in which it was contained.

Observations.—At 243° not a perceptible trace of chlorine was given off. After the lapse of fifteen minutes, at 250°, the nitrate of silver, into which the gas was conducted, was observed to be slightly milky; this may, therefore, be taken as about the temperature at which chloride of copper begins to suffer decomposition. At 267°, a solution of nitrate of silver was instantly precipitated.

Thinking that perhaps the small quantity of chlorine evolved under these circumstances might be taken up again and retained if oxide of copper were present, and possibly, also, that in that case a higher temperature might be safely employed—to make the conditions of the experiment conform in this particular to those which exist in an analysis, all but one inch of the chloride of copper was removed from the tube, and in its place was put a mixture of asbestos and oxide of copper, occupying a space of four inches in length, forward of the chloride. The experiment was then repeated. Prolonged heating in a current of air, and afterwards in oxygen, during which the thermometer rose to 350°, produced no reaction with nitrate of silver. From this it appears that the chlorine, which is given off below this temperature from chloride of copper, when this is mixed with oxide of copper, is absorbed and retained by the latter; hence, that so high a temperature as 350° may be safely employed for the air-bath in conducting an analysis by this process.

Analysis 1.—In this analysis the oxide of copper employed was prepared in the ordinary way and strongly ignited. The space in the tube occupied by the mixture of asbestos and oxide of copper was five inches in length, and contained just five grammes of the oxide. During the experiment, the temperature of the air-bath was maintained at about 350°. At the close of the combustion there was no appearance of chloride of copper, except in the first half inch at the back end of the column of the mixture of oxide of copper and asbestos, showing that the temperature employed was favourable for rapid and complete absorption of the chlorine.

Results of the Analysis.—0·1682 gramme of chloride of amyl gave 0·3486 of carbonic acid, 0·1633 of water, and 0·2233 of chloride of silver.

		Calculated.		Found.
Carbon .	C_{10}	60	56·3910	56·522
Hydrogen .	H_{11}	11	10·3383	10·761
Chlorine .	Cl	35·4	33·2707	32·773
			100·0000	100·056

Analysis 2.—The oxide of copper employed was of the same preparation as that used in Analysis 1. The space occupied by the mixture of asbestos and oxide of copper was only three and a half inches in length, but contained the same quantity—viz., five grammes of the oxide of copper—as used in the previous analysis. The temperature of the air-bath ranged from 250° to 253°. At the close of the combustion, it was found that all but three-quarters of an inch at the forward end of the column of mixed asbestos and oxide of copper had the appearance of containing chloride of copper. By comparison with the corresponding observation in Analysis 1, it will be seen that the appearance of the chloride extends over more than five times the space in this analysis that it did in the former, showing that with strongly ignited oxide of copper a temperature higher than 250°, even as high as 350°, is more favourable for the absorption of the chlorine. The following results of the analysis, however, are equally accurate with those of the preceding analysis.

0·1669 gramme of chloride of amyl gave 0·3457 of carbonic acid, 0·1612 of water, 0·2213 of chloride of silver.

		Calculated.		Found.
Carbon .	C_{10}	60	56·3910	56·489
Hydrogen .	H_{11}	11	10·3383	10·785
Chlorine .	Cl	35·4	33·2707	32·732
			100·0000	100·006

Analysis 3.—Under the impression that an oxide of copper which had been strongly ignited might be effectual to absorb the chlorine at a lower temperature, I employed in this and the two following analyses a preparation of brown oxide of copper, obtained by precipitation with potash and ignition over an ordinary gas flame. In this analysis the temperature of the air-bath ranged from 150° to 158°. The space occupied by the asbestos mixture was 4 inches in length, and contained 3 grammes of the oxide. Although the results of the analysis indicate that the temperature of the air-bath was too low, they also show, by comparison with the results obtained in operating with strongly ignited oxide at about the same temperature of the air-bath, that the brown oxide is decidedly preferable in respect to the temperature required. This was also shown by the appearance of the oxide after combustion—the newly formed chloride being confined, in the case of the brown oxide, to a much shorter space.

Results of the Analysis. — 0·1640 gramme of chloride of amyl gave 0·3504 of carbonic acid, 0·1562 of water, and 0·1884 of chloride of silver.

		Calculated.		Found.
Carbon .	C_{10}	60	56·3910	58·268
Hydrogen .	H_{11}	11	10·3383	10·582
Chlorine .	Cl	35·4	33·2707	28·360
			100·0000	97·210

Analysis 4.—Used the same preparation of oxide of copper as in Analysis 3, viz., the brown oxide. Temperature of the air-bath reached 170°. Slight carbonisation occurred just at the close of the combustion, from extending the heat backward too soon, under a wrong impression that the substance was all burnt. Were it not for this circumstance it is believed that this would have been a good analysis, although the temperature of the air-bath was kept so low. That a higher temperature of the bath is desirable, however, is shown by the fact that the chloride of copper appeared diffused over a space of $2\frac{1}{2}$ inches. The length of the column of mixed asbestos and oxide of copper was only four inches in this experiment, containing but one gramme of the oxide.

Results of the Analysis. — 0·1568 gramme of chloride of amyl gave 0·3195 of carbonic acid, and 0·1522 of water.

		Calculated.		Found.
Carbon .	C_{10}	60	56·3910	55·574
Hydrogen .	H_{11}	11	10·3383	10·784
Chlorine .	Cl	35·4	33·2707	

Analysis 5.—The oxide of copper employed was of the same preparation as that of Analyses 3 and 4. The temperature of the air-bath, however, was considerably higher, ranging from 240° to 247°. The mixture of asbestos and oxide of copper occupied a space of five inches in length, but contained only two grammes of the oxide. At the close of the combustion there was no appearance of chloride of copper, except at the back end of the column, a space of three-quarters of an inch in length.

Results of the Analysis.—0·1631 gramme of chloride of amyl gave 0·3383 of carbonic acid, 0·1557 of water, and ·2157 of chloride of silver.

		Calculated.		Found.
Carbon .	C_{10}	60	56·3910	56·542
Hydrogen .	H_{11}	11	10·3383	10·607
Chlorine .	Cl	35·4	33·2707	32·649
			100·0000	99·798

It can hardly have escaped observation that the quantity of oxide of copper or oxide of zinc required to absorb the chlorine by this process is extremely small, in consequence of its being uniformly diffused through a large mass of asbestos; hence it is obvious that but little of a solvent is needed to extract the chloride. In this respect the new process bears a striking contrast to the old one, which involves the use of a large quantity of lime, necessitating a corresponding quantity of acid, and introducing disagreeable manipulation, which tend to increase the liability to error.

I have not yet tried the process recently described by Carius,† as the difficulty which I had found in obtaining tubes that would bear the pressure incident to his process for the determination of sulpuur gave no encouragement of better success in the use of his process for the determination of chlorine, which is performed in a similar manner, although more complicated.

The advantage which my process affords, of being able to determine the three elements carbon, hydrogen, and chlorine at a single combustion, without the introduction of any difficult or hazardous manipulation, induces the belief that it will be found preferable to any other that has been devised.

FOREIGN SCIENCE.

(From our own Correspondent.)

Paris, February 26, 1867.

At the last meeting of the Photographic Society of France, M. Decagny expressed the very correct opinion that too much attention is generally paid to the iodising of the collodion; that it should be devoted almost entirely to the developer, and, thanks to that, we can obtain the same rapidity with the dry collodion process as with the wet process. In corroboration of this idea he showed proofs taken with very small diaphragms, a very feeble light, and a relatively short time of exposure; they were remarkably sharp and clear, as regards perspective and relief, and their perfection was due to a mode of development suited for a dull light.

M. Klein presented a new enlarging apparatus on Woodward's principle, but which he considers he has greatly improved. The light is produced by four lenses—two before and two behind the proof; the object-glass is suppressed, and there is no spherical aberration. The operation can be carried on in clear weather, without direct sunshine. With salted or albuminised paper a positive proof of perfect clearness can be printed in twenty-five minutes on a sheet 45 by 57 centimetres, and in forty or fifty minutes on a double sheet.

M. Pinel-Pechardière presented several specimens of chromo-lithographic impressions vitrified upon different organic substances, accompanying them with the following note:—In order to vitrify a photo-lithograph by the processes of sprinkling or stencilling employed in porcelain, earthenware, or glass decoration, a single design is not sufficient in general, even when it relates to a monochromic image; two are necessary. In order to obtain, in varied colours, a monument, view, &c., it is absolutely necessary, as in chromo-lithography, to have a design on stone for each colour. All these designs are obtained on the stone, by solar radiation, from a single proof. On his part, M. Dagron, of 66, Rue des Petits-champs, Paris, has shown us porcelains, earthenware, crystal glass, with portraits and photographic views of a beautiful effect, which he obtained by a very simple, efficacious, and economical process. He is only waiting for more brilliant results to produce them on a large scale.

† *Annalen der Chemie und Pharmacie.*

M. Charles Nègre, of Avignon, mentioned that he has followed up his process of heliography on steel. The steel plate, covered with Judean asphalte, or a layer of gelatine mixed with bichromate of potash, is printed upon by the sunlight through the wrong side of a negative obtained directly in the camera; thus, the coating of varnish being impressioned by the parts which correspond with the shadows of the proof, the steel plate is exposed in the parts which correspond with the lights. Steeped in a gold bath, and submitted to the action of a current of electricity, the steel plate receives a uniform layer of gold on the parts corresponding to the lights of the proof; while the portion covered by the shadows, covered with sensitised varnish, only becomes covered with the particles of the gold in proportion to the intensity with which the light has acted in the different tints and in the tones of the shadows. On removing the coating of varnish from the steel plate, it presents only an image formed by a deposit of gold, perfectly inherent—a truly shaded sort of Damascus work. The gold being unattackable by acids, all that is necessary is to pour on the plate diluted acid, in order to obtain an engraving presenting all the shades of tint, from the clear white of the paper to the deepest black, at the same time preserving the precision, fineness, and sharpness of outline of the photographical proofs. The steel plate thus engraved, being able to furnish a great number of proofs, will be able to give faithful proofs on subjects of history, archæology, natural history, and all the sciences which require drawings of a mathematical exactness. The plates thus prepared can also be improved, added to, or altered in any way the artist may choose—an immense advantage, which a photographic proof does not possess.

Steam Ice Machines of M. Toselli, 236, Rue du Faubourg Saint-Martin.—We had scarcely mentioned the complete success of the steam refrigerators of M. Toselli when H.M. the Emperor of the French expressed a desire, through General Favé, of seeing this ingenious machine at work in the Palace of the Tuileries. M. Toselli having attended and performed the experiment, the Emperor expressed his perfect satisfaction as to the simplicity and efficacy of the mechanism. An ice-producing machine capable of forming 22 lbs. of ice per hour, or nearly 2 cwts. per day, is a square parallelopiped 9ft. 2in. long, 6ft. 3in. wide, and 6ft. 5in. high. It consumes four centimes (nearly a halfpennyworth) of charcoal for every kilogramme of ice formed, and only requires the attention of one man to set it at work, and to give the necessary movement to the circulation of the water. The machine costs 1801., and can be delivered two months after the order.

In our impression of the 22nd inst. the writer of this article threw out some very justifiable hints as to the delay in the awarding of the prizes of the Society of Encouragement of Paris. The evil has been remedied, and M. Dumas, having frankly acknowledged the injustice of irregular distributions of rewards, declared that henceforward they should take place at the first January meeting, and that two meetings should be held every year—one for recompenses, and another for prizes—on independent days specially reserved, and placed entirely under new conditions. Our voice has been heard, and we thank M. Dumas for his *amende honorable*. The following medals were distributed on the 20th inst.:—

Gold Medals.—Achard, for his electric break for railway carriages. The report was read by M. Tusca in his usual clear voice, and with a description so lucid that even the model (which was in the hall) was not referred to.—M. de Clermont, for hat fur procured from rabbit skins by a machine of his own invention, which shaves the hairs off and puts them in order for manufacture.—M. Paris, for his works in enamelled bronze.—Rattier, for his submarine telegraphs.—Serrin, regulator for the electro-magnetic light.—Tailbouis, sewing machine.—Wulveryck, woollen goods, white and printed.

Platinum Medals.—Bosio, clock with free escapement.—Castelnau, special instruction for public works.—Groust, economical vegetable soups.—Gillou, jun., and Thorailler, paper-stainers.—Lauth, for aniline black.—Lambotte, drawings of flowers and horticulture.—Chambon-Lacroisade, stove for heating smoothing irons.—Nauden, holosteric barometer.

F. Moigno.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, February 21.

Dr. A. W. Williamson, *F.R.S., Vice-President, in the Chair.*

The following gentlemen were duly elected Fellows of the Society, viz.:—Mr. R. H. Davey, of the War Office, Pall Mall; Mr. Jonathan Hearder, Plymouth; Mr. Henry Watson Eve, M.A., Wellington College, Wokingham; Mr. William Thurston Waite, 37, Jewry Street; Mr. Martin Henry Payne, 47, Mortimer Street, Cavendish Square; and Mr. Frederick George, of Cheltenham. The candidates proposed were—Angus Fraser, M.A. and M.D., Aberdeen; Frederick S. Barff, M.A. Cantab., 16, North Audley Street, Grosvenor Square; and Mr. Alfred Tribe, of Great Portland Street. For the second time were read the names of Major R. C. Stewart, Deputy Assistant Adjutant-General to the Forces, Horse Guards, and 12, Prince of Wales' Terrace, Kensington Palace; Mr. James Campbell Brown, 65, Bon Accord Street, Aberdeen; Mr. William Price Bonner, 69, Mark Lane; and J. Hersee Freeman, Stratford House.

The Chairman announced the Council's proposition referring to the election of officers for the year ensuing, and, agreeably to the by-laws of the Society, the names will be read at three successive ordinary meetings before proceeding to the ballot on the occasion of the anniversary meeting, March 30. The retiring officers were, the President, Dr. W. A. Miller, to be succeeded by Dr. Warren De la Rue; Dr. J. H. Gladstone, to be a Vice-President, in place of Dr. De la Rue; the ordinary members of Council who retire are Professor Debus, Dr. Letheby, Dr. Hugo Müller, and a vacancy has arisen by the death of Mr. Hadow. The names of four gentlemen proposed for election are Mr. J. L. Bell, of Newcastle; Mr. David Forbes, Dr. Matthiessen, and Professor Wanklyn.

The Chairman stated that a wish had been expressed, both in the Council and by other Fellows of the Society, to the effect that a social gathering should take place at a convenient date previous to the anniversary meeting. It had been proposed to dine together at the Albion Tavern, Aldersgate Street, on Wednesday, March 27.

A paper on "*Limited Oxidation: Determination of the Oxygen Consumed,*" was read by Mr. E. T. Chapman. The author stated that, under the influence of chromic acid, a very small amount of splitting up in the acids of the acetic series would be accompanied by a large absorption of oxygen. When, therefore, it is shown that the theoretical amount of oxygen is consumed in the conversion of an organic substance into an acid of the acetic series, it is at the same time proved that no splitting up of the acid or acids produced has taken place. It is demonstrated by quantitative experiments quoted in the paper, that in the cases of butyric ether, propione, and diethoxalic acid, the amounts of oxygen do so coincide with the calculated numbers. The determinations were made by titrating the chromic solution with oxalic acid, and weighing the liberated carbonic acid. A known quantity of this solution was then digested with a known weight of the organic body, and after the digestion the solution titrated in the same manner; the difference between the two amounts of carbonic acid is the measure of the oxygen consumed.

These determinations give the most complete control over the analyses performed by gradual oxidation. The author mentions that estimations of alchohol may be made with certainty by determining the amount of oxygen required by a given weight of the alcohol; and concludes by recommending the adoption of his process as a proved method in a great variety of quantitative examinations.

Dr. Hugo Muller inquired whether this method was applicable to the examination of members of the aromatic series.

Mr. Chapman stated, in reply, that benzoic acid resisted the action of the chromic solution as well, or nearly as well, as acetic acid. Experiments of the kind had been already made by Mr. R. H. Smith, who worked both upon the ethylic and methylic benzoate.

Dr. Odling wished to know whether, in the examination of hydrocarbons of the group C_8, any specific degree of solubility was requisite, or any particular strength of chromic solution to be employed by preference, having regard to the necessity of avoiding the breaking up of the primary molecule.

Mr. Chapman had made a few trials with amylene, β-hexylene, &c., and found the use of a strong solution with a moderate heat advantageous. It might be possible to dissolve the organic body in acetic acid, or other solvent not itself attacked, before acting upon it with the chromic solution.

Dr. Muller suggested that the expedient of first converting them into sulpho-acids might sometimes be followed. MM. Fittig and Beilstein had already treated xylol with nitric and also with chromic acid, and obtained two acid products.

Mr. Chapman said that it was important to guard against the presence of free sulphuric acid in these oxidation processes, for the least excess exerted an action on its own account.

Professor Wanklyn described the apparatus used in the laboratory of the London Institution for the heating of long glass tubes in these and similar experiments. They are laid *horizontally*, whereby an immensely increased surface of contact between two non-miscible liquids is gained, and the heat is applied by an outer steam-jacket.

The Chairman moved a vote of thanks to the author and, at an early hour, adjourned the meeting until March 7

ROYAL INSTITUTION OF GREAT BRITAIN.

Friday, February 15, 1867.

The lecture theatre of the Royal Institution was crowded on Friday evening, the 15th, to hear a discourse, by Mr. Cromwell Varley, on the Atlantic telegraph. On the table there were displayed coils of the cable successfully laid last year, and of the cable which had been picked up from a depth of two miles, having lain at the bottom of the sea for twelve months.

Mr. Varley did not enter into the consideration of the mechanical construction of the cable, nor of the plan of laying it down, but confined himself to the scientific part of the subject, and to the explanation of the difficulties which arise in attempting to transmit electric signals through great lengths of submerged insulated wire. By means of his artificial cables he demonstrated for the first time in public how the electric waves travel through. He also showed what were the limits imposed by nature to rapid signalling.

A submarine cable is a long Leyden jar whose inductive capacity depends upon the specific inductive capacity of the insulator (gutta-percha), and upon the quantity used. He explained that for a given diameter of gutta-percha core, the highest speed of signalling was attainable when the ratio of the gutta-percha was to that of the conductor as $\frac{1}{6}$. The ratio of the Atlantic cable was a little more than $\frac{3}{1}$. To double the speed of such a copper conductor, it would be necessary to apply a second covering, whose diameter was $(\frac{3}{1})^2 = 9$, and to treble it a third coat, whose diameter was $(\frac{3}{1})^3$, was required, and so on. This was expressed generally as follows:—

Thickness of dielectric in flat plates between equal conducting surfaces $= d$.

Quantity of electricity absorbed by electro-static induction $= Q$.

$$2d = \frac{Q}{2} \qquad 3d = \frac{Q}{3} \qquad nd = \frac{Q}{n}$$

Cylindrical conductors whose exterior surfaces increase with the diameter.

Thickness of dielectric $= d$.

Quantity of electricity absorbed by electro-static induction.

Ratio of exterior and interior surfaces $= r$.

$$d = Q'$$
$$d + dr = \frac{Q'}{2}$$
$$d + dr + dr^2 = \frac{Q'}{3}$$
$$d + dr + \ldots\ldots dr^{n-1} = \frac{Q'}{n}$$

and generally

$$d + dr + \ldots dr^{n-1} = d\left(\frac{r^n - 1}{r - 1}\right) = \frac{Q'}{n}$$

Light and radiant heat travel through space with a definite velocity—electricity does not. The waves of light do not flatten out or elongate during their flight over millions and millions of miles. For example, suppose the star Sirius were suddenly covered with a screen for ten minutes and then uncovered again, the star would still appear on this earth to shine continuously for about twenty years after the screen was applied, when it would suddenly be extinguished for just ten minutes and then reappear.

Electricity, in passing through a cable, begins instantly to appear at the distant end, but in strength far too weak to be measured. After the lapse of a certain time, definite for each particular cable, it begins rapidly to augment in power, and continues to approach to a definite limit of strength.

Electricity is popularly supposed to have a definite velocity, like light, but it is not so. The question, "What is the velocity of electricity?" cannot be answered without other conditions are given. For instance, it begins to arrive at the distant end instantaneously; but to reach its maximum strength would, strictly speaking, require eternity and a day, while to reach half its maximum strength would have occupied a time of $6a$—this quantity a being a definite time dependent upon the dimensions of the cable.

In 1854 Dr. Faraday gave a lecture, in which he described a number of experiments which he had made with 100 miles of gutta-percha-covered wire, and also some experiments upon 1500 miles of line between London and Manchester. But on the table before the lecturer was an artificial representation of a cable 13,000 miles in length, by the aid of which the same phenomena amplified, and many others, were exhibited.

A telegraphic cable is a long Leyden jar, one end of which is attached to the earth whilst the other is attached to a source of electricity each time a signal is to be produced. If the cable be connected to a battery for a long time, the strength of the charge in the different parts of the cable will be nothing at the end next the earth, and equal to the full power of the battery at the other end. The charges in the other parts of the cable were shown by a right-angle triangle, the diagonal line representing the potential or charge in the different parts of the cable.

The lecturer had diagrams showing the rate at which the strength of the electric currents augmented or died away at the distant end of the cable when a battery was

applied or removed from the other end. From these diagrams and experiments it was shown that to get rapid signals the receiving instrument must be very sensitive, and the moment a current begins to appear at the distant end the rest of the electric wave must be neutralised to permit a second signal to follow. This was illustrated by an artificial line equal to a cable like the Atlantic, 13,000 miles long.

This line was divided into eleven sections, and ten reflecting galvanometers were inserted at equal distances along it.

To familiarise the audience with the relative position of the galvanometers, Mr. Varley called No. 1 Gibraltar; No. 2, Malta; 3, Suez; 4, Aden; 5, Bombay: 6, Calcutta; 7, Rangoon; 8, Singapore; 9, Java; and 10, Australia.

A long telegraphic cable is a long Leyden jar of great resistance—so great that instead of electrical charges rushing in and out almost instantaneously, as is the case with ordinary Leyden jars, an appreciable time is necessary to convey a decided charge through so long a conductor to the distant end. The artificial representative consisted of eleven resistances and ten immense condensers, or Leyden jars, connected between the resistances and the earth. There was also an artificial representative of the Atlantic cable. The latter consisted of eleven resistance coils, the former of eleven glass tubes filled with water connected in series. By moving a handle the condensers could be applied to, or removed from, these junctions.

On depressing an ordinary commutator key, the cable was removed from its connexion with the earth, and a positive current allowed to flow into the line. On depressing a second key, a negative current rushed in; whilst, when both the keys were at rest, the cable was simply connected with the earth. The ten reflecting galvanometers were placed one above the other, and a bundle of rays from the electric lamp was thrown upon the ten mirrors, each of which reflected a little sun-like spot upon a large white screen, forming, when no current was passing through the cable, a straight vertical line of luminous points. On pressing the right hand, or positive key, the upper spot, which was named Gibraltar, almost immediately responded; and when it had travelled about thirteen inches over the screen, the second spot, Malta, began visibly to move, the third Spot, Suez, following later still. It was, however, fifteen or sixteen seconds before any decided motion or current was noticed at the Australian end of the line. After the lapse of a minute, a powerful current was rushing out at the Australian end. The English end was then removed from the battery, and connected with the earth, and quickly after the Gibraltar spot rushed across to the other side of the screen, indicating the rushing back of a powerful current to the earth. This was followed shortly afterwards by Malta, Suez, and Aden. Bombay came only as far as the zero line. The currents in the different parts of the cable were flowing out at each end, leaving Bombay neutral. It was some minutes before the cable discharged itself sufficiently to allow the ten spots to come near enough to the zero line to admit of a second experiment.

When a succession of signals was sent into the cable by alternately depressing and elevating the key, for periods of five seconds each, these impulses produced waves which could be distinctly traced as far as Aden, where their individuality became lost. The little spots beyond this station showed the presence of a current resulting from the combination of these successive waves. Mr. Varley then pointed out the methods of clearing the line after each impulse. In 1853-54 he invented a plan which consisted of sending after each positive current a negative current—a plan which is now generally used in working submarine lines, except the Atlantic.

In 1856 he invented a plan which consisted of sending a strong positive current of definite duration into the line, followed by a weak positive current to produce a signal, this being followed by a strong negative current, succeeded by a weak negative current to clear the line. This system was a great improvement upon the former.

In 1858 Professor Sir William Thomson proposed the use of three currents of equal duration but irregular strength and alternate signs, which produced a still more rapid result.

In 1863-64 Mr. Varley found, by experiments on his artificial line, that by using a succession of four or five currents, all of the same strength but varying in duration, greater rapidity could be secured. For example, first a positive current, followed by a negative of longer duration, followed again by a positive current of much less duration, then a shorter negative current, and that again by a very short positive current, produced a succession of positive and negative waves throughout the line; the result of all of which was at the Australian end one very small positive wave, perfectly distinct, the rest of the line being left almost immediately entirely free from all traces of electricity, ready for the instant production of a second signal.

The lecturer roughly calculated the proper duration of the currents by the aid of a watch, and the luminous diagram showed how the line was filled with a succession of positive and negative waves, each of which quickly neutralised its neighbours.

This operation of discharging has been expedited to such an extent by means of the instrument known as the "curb key," that the great wave can be arrested at the distant end of the cable before it has arrived at $\frac{1}{200}$ of its proper height, and the line left clear for another signal almost immediately after. This was illustrated by the Australian line.

When the condensers were removed from the line—which was equivalent to lifting the cable out of the ocean—the ten stations gave simultaneous and apparently instantaneous electric indications.

This was very prettily illustrated on the artificial Atlantic cable, by placing a Geisler's vacuum tube in the place of a telegraph instrument at the "Newfoundland" end of the line.

This tube was found by experiment to resist the passage of an electrical current until its strength amounted to somewhere between 390 and 400 Daniell's cells. A battery of 800 Daniell's cells was connected with the cable, after which several seconds elapsed before any indication of its having reached Newfoundland was visible in the Geisler's tube; but as soon as the power at that end amounted to half the power of the battery at the English end, a beautiful violet flame was seen illuminating the tube.

The English end was then suddenly connected with the earth through a second Geisler's tube, when both tubes were seen shining brilliantly at first, but gradually declining as the charge in the cable decreased.

The Newfoundland end of the cable was the first to go out, and the English end continued to shine for a second or two after, because the potential of that end, when first connected with the Geisler's tube, was greater than that of the Newfoundland end, because it was nearest to the battery. The moment the condensers were removed, the speed was instantaneous. When the condensers were charged with the 800 cells, and discharged through a piece of tinfoil, a brilliant splash, a loud report, and a hole in the tinfoil half an inch in diameter was the result.

The lecturer then showed his invention for preventing the disturbance arising from earth currents, and for expediting the signals through the cable, which did not record the strength of the current, but "the rate of increment and decrement of potential."

He placed a reflecting galvanometer between the distant or "Newfoundland" end of the cable and the earth (this being the usual mode of connecting telegraph instruments), and also a second one with a "condenser" between it and

the earth. At the English end there was an apparatus which produced currents through the cable similar to those produced on telegraph circuits by the Aurora Borealis and other causes. These experiments were very conclusive; the slow but large wave of the earth current was seen to produce scarcely any action upon the galvanometer with the condenser, while the ordinary one was seen running 20 feet on either side of the scale, in consequence of the earth currents.

The small waves on the back of the great swell of the earth currents were, however, perfectly disentangled, by this simple contrivance, from the great slow-rising wave, and the signals were perfectly legible on the one instrument while illegible on the other, whose image ran wildly over the wall of the Institution. In addition the signals were transmitted more rapidly and clearly by this arrangement.

In concluding, Mr. Varley remarked that it was upon the data furnished by this artificial cable that he had designed the present Atlantic cables, and that without it he could not then have guaranteed eight words a minute without a core whose conductor and insulator were each 60 per cent. greater than the present, which consisted of 300 lbs. of copper and 400 lbs. of gutta-percha to the mile; and he added that it was at least some reward for the years of arduous labour he had had in connexion with this great enterprise, to find that everything he had predicted as to the capabilities of the cables had been entirely verified.

SOCIETY OF ARTS.

On the Synthesis and Production of Organic Substances and the Application which some of them receive in Manufactures, by Dr. F. Crace Calvert, *F.R.S., F.C.S., &c.*

Lecture II.

On the Transformation of Neutral Substances.

The object in this evening's discourse is to invite you to examine with me the valuable, varied, and curious transformations which one substance is capable of undergoing, and which have been brought out through the study of its chemical nature and composition; and what, I hope, will render these transformations especially attractive is the fact, that they have reference to the reproduction of substances which are either found abundantly in nature, or which have received numerous and useful applications in arts and manufactures. The substance which I refer to is starch, a white, granulated substance, insoluble in water, which undergoes no change or decay, if kept dry, even for centuries, but which, when damp or brought into contact with water, rapidly undergoes decay. Starch, when boiled for a few minutes with eight or ten parts of water, and the whole allowed to cool, forms a jelly, which gives a magnificent blue colour with iodine. This colour has been the subject of much study by chemists, owing to the fact that it disappears when heat is applied to it, and that it reappears as the liquor cools. It is so brilliant that many attempts have been made to apply it in some form or other in arts and manufactures; and in some of my previous lectures I have described some of them. Starch, as you are aware, is most abundantly found in nature, especially in the grains of cereals, such as wheat, barley, oats, &c.; it exists also in large quantities in bulbs, such as potatoes; and in leaves, fruit, stems, and roots. It is easy to conceive that such a substance should have been devised by the Creator, first to preserve and then to feed the young germs contained in seeds; for, as I have just stated, it is unalterable by time if kept in a dry condition, whilst it undergoes the most rapid transformations if placed under certain circumstances, or if it comes in contact with certain chemical agents. Of this we shall have, as we proceed, most interesting instances, especially when we examine the transformations which starch undergoes during the germination of seeds and in the ripening of fruits; but, to enable you to understand thoroughly these transformations, allow me to call your attention to some of the transformations which starch undergoes by purely chemical action, and then we shall apply them with better success to the chemical changes which take place in nature under vital action.

When starch is mixed with hot water, and a few thousandths of an acid, especially vitriol, are added, the globules of the starch are swollen; they burst; and the more soluble portions of the amylaceous matter are transformed into what is called soluble starch, the liquor losing its opaque appearance and becoming transparent. I may mention that it is a similar transformation that renders the Glenfield patent starch so much appreciated for stiffening net and other similar fabrics, owing to the circumstance that they are stiffened without becoming opaque. Let us now proceed to examine what takes place if the proportion of acid is slightly increased, and the heat continued for a short time; we shall find that the starch is susceptible of undergoing a further molecular change, the liquor assuming a slight yellow tinge, and instead of giving with iodine a bright blue colour it yields a rich crimson, the starch having become converted into what chemists called dextrin. This transformation is purely molecular; nothing is added to or subtracted from the original elements of the starch. But if, instead of stopping the operation at this point, we still continue to boil for, say, three or four hours, we shall find that the liquor will gradually cease to yield a colour with iodine, and when it has entirely ceased to do so, if we neutralise the slight acidity of the liquor by adding to it a little chalk, and by filtration remove the gypsum deposit, we shall observe that the liquor has a decided sweet taste, and that we have transformed the starch into glucose, or what is often called grape-sugar because it is found in grapes, fruit-sugar because it is found in most fruits, diabetes-sugar because it is found in diabetes. This interesting transformation of starch into sugar is carried on, on the Continent, on a most extensive scale, thousands of tons of glucose being manufactured annually, which are used by brewers as a means of producing a cheap and frothy beer; and allow me to add, "under the rose," that it is also employed—and that not with advantage to the consumer—to adulterate honey. In England glucose is not manufactured, in consequence of the restrictions imposed on it by Government and the excise laws, but I must not forget to state that when the transformation of starch into glucose is effected on a commercial scale, the apparatus employed is such as to enable the manufacturer to use a slight pressure, experience having demonstrated that this transformation is much more rapid under the influence of a slight increase of pressure, and therefore the manufacturer avails himself of it. You will remember, no doubt, that in several of my previous lectures I have drawn your attention to the fact, that many chemical transformations are brought about or facilitated by an increase of pressure, easily obtained when the mass acted upon is confined in vessels so constructed as to prevent the vapours from escaping.

The transformation of starch into dextrin is also effected by other means. Thus, if it is submitted to the action of a heat of about 400°, it undergoes the same isomeric change, and is converted into dextrin; this transformation is most important, and is carried on, on a most extensive scale, in Lancashire and the north of England, a cheap substitute for gum-arabic being thus placed in the hands of calico printers to thicken their colours, and to enable the workman to apply them on the surface of fabrics, either by means of rollers or engraved blocks. As the orange-yellow colour assumed by wheaten starch and potato farina under the influence of heat is often objectionable in a practical point of view, manufacturers mix the wheaten starch, or the farina, with a small quantity of

acid, and, after having dried the whole, submit the mass to a comparatively low temperature, when the transformation of insoluble starch is effected, and soluble dextrin, nearly colourless, or patent gums, as they are called, are produced. For more technical details I must refer you to a paper which I had the honour of reading on the subject a few years since before this Society.*

It is scarcely necessary that I should state that starch is converted into dextrin and then into sugar under the influence of peculiar ferments. You will, I am sure, remember that I explained these transformations when speaking of the action of the saliva, and also that of the pancreatic glands, in my lectures on animal physiology last year. You are also, I know, perfectly aware that it is a similar transformation which takes place in the brewer's vat under the influence of the albuminous ferment called diastase, when malt is converted into the saccharine fluid which is called "wash," and which is ultimately converted, by boiling with hops and fermentation, into that national fluid called beer or ale. With these facts before us we can not only appreciate the value of starch in seeds, plants, and fruits, but follow with interest the changes which it undergoes in order to become useful in the germination of the young plant, or in the ripening and sweetening of fruits. Most seeds—indeed, I may say, all seeds—contain essentially two elements, one called starch and the other albumen, a substance, as you are aware, which in the animal kingdom characterises the white of egg and the serum of blood. When a seed is placed in moist soil, and a gentle heat surrounds the whole, the albumen undergoes a molecular modification, and becomes a ferment, which differs from common albumen by the fact that it requires a much higher temperature to coagulate it. Under the influence of this ferment and the joint action of heat and the moisture which surrounds the seed, the starch is converted first into dextrin, and then into sugar—or, in other words, into such substances as are soluble, susceptible of being absorbed, fixed, and transformed into such elements as will constitute the tissues of the young plant. I shall have the pleasure of showing you, as we proceed with this lecture, that when one chemical equivalent of starch has fixed two equivalents of water, and has thus been converted into sugar, it can unfold itself with great facility into either three equivalents of acetic acid or two equivalents of lactic acid, as shown by the following table :—

Sugar	$C_{12}H_{12}O_{12}$
Acetic acid, three equivalents .	$C_4H_4O_4$
Lactic acid, two equivalents .	$C_6H_6O_6$

These acids, or similar ones, dissolve the lime and other mineral matters surrounding the seed, thus carrying to the young germ those mineral elements which it required to become a young plant, which, when once it has grown out of the seed and of the soil which surrounds it, puts forth leaves, which are susceptible of absorbing the carbonic acid of the atmosphere, thus fixing its carbon, which constitutes the framework of the young plants. This carbon, united with the elements of water and nitrogen, gives rise to all the vegetable substances necessary to constitute the vegetable matter of full-grown plants.

The ripening and the sweetness of fruits are due to the conversion of starch into sugar; but although this conversion is effected by the presence of acids in the fruit, still they are not exactly the same as those which exist in the young seed, and therefore this peculiar transformation of starch into sugar in fruits deserves our special notice. The predominant acid in green fruit is called malic acid, which partly disappears as the fruit proceeds towards its maturation, whilst the greater part unites with the sugar it has helped to produce.

In fruits and in bulbs there exists another substance which presents to us a peculiar interest. It is a white, gelatinous mass, insoluble in water, and is called pectose. It is also accompanied in fruits and bulbs by its ferment, called pectase, the same as starch is accompanied by its ferment, called diastase. As time proceeds, the pectase acts upon the pectose, and converts the insoluble substance pectose into the soluble substance called pectine, which is a neutral substance, but which in its turn is converted into an acid called pectic acid. This acid, in connexion with malic acid, sometimes converts the starch contained in fruit into sucrose, or cane sugar, fructose, or fruit sugar, which I may here state differs from cane sugar in not crystallising with the same freedom, is not so sweet, and also contains two chemical equivalents more of water. The transformations of pectose into pectine and pectic acid are isomeric changes, and therefore are most easily effected in nature. The following table will clearly demonstrate the truth of this assertion :—

Pectose	$C_{64}H_{40}O_{56},8HO$
Pectine . . .	$C_{64}H_{40}O_{56},8HO$
Pectic acid . .	$C_{64}H_{40}O_{56},4HO$
Metapectic acid. .	$C_{64}H_{40}O_{56},16HO$

(To be continued.)

ACADEMY OF SCIENCES.

February 18, 1867.

(From our own Correspondent.)

The news of the death of Madame Pelouze, which took place almost suddenly in the night of the 17th-18th inst., spread a gloom over the proceedings of the Academy in the Hall of Sciences, where the illustrious chemist possessed as many friends as professional brethren. Each feels that he loses the most excellent of companions, and takes a lively part in the general grief.

An amateur astronomer has recalculated the elements of the comet recently discovered at Marseilles, and finds some resemblance between it and the comet of 1771.

The Baron de l'Epine gave some details on the ossiferous beds discovered by him in the grottoes or caverns above the Lac de Bourget, in Savoy. He found there human bones and those of carnivorous animals, fragments of bricks similar to those which enter into the construction of the Roman hot baths of Aix, which date as far back as the second century of our era.

M. Henri Sainte-Claire Deville analysed in a few words a new note on the density of vapours. It refers to the chlorides of niobium and tantalum; and the results obtained by the celebrated chemist agree in every respect with those of M. Marignac, of Geneva.

M. Dumas presented the hydrological map of the department of the Seine, very carefully got up by M. Delisle, engineer of mines. A great innovation is, that M. Delisle gives at every five metres the depth at which, by sinking a well or boring, one is sure to find water; it is an immense service rendered to proprietors and manufacturers.

M. Combes, Director of the Imperial School of Mines, presented to the Academy a book which he has just published, through Bouchard-Huzard, under the title of "Essay on the Mechanical Principles of Heat, and of its Practical Applications." "My aim," said the author, "is to popularise among engineers and constructors of machines a theory to which they cannot remain much longer strangers, and which should, in fine, pass into the instruction of our schools. Consecrated, at the present day, by its accordance with phenomena observed since it has been established, as well as with facts anciently known, of which it alone furnishes a sufficient explanation, it brings to light the enormous losses of heat which take place in our steam engines, even the most improved, shows the progress which remains to be made, assigns its limits, and will lead, no doubt, to its realisation. . . I have, above all, had a view, in the editions of this work, to simplicity and clearness. I confine myself to the exposing the general

principles, the facts which appear at present definitively established in science, and the practical consequences which follow therefrom.

M. Davanne sent his photographic annual for 1867, published by M. Gauthier-Villars. It is an excellent little volume, which contains, in a convenient form, a mass of useful information, which photographers and chemists will with difficulty find elsewhere. Printed upon strongly sized paper, it will bear all observations to be written in ink; and a few blank pages left expressly in the formulary are very convenient to receive any modifications that practice may suggest. The first portion gives the general state of the photographic world, societies, sciences, meetings, recompenses, patents, publications, and journals. In the second part, the author gives a comparative essay upon the most brilliant facts and the important progress which have taken place during the preceding year, with indications of the sources from which they have been obtained. The third part comprises a general formulary for the wet and dry negative processes, with tables very useful to the photographer desirous of making his own preparations or of verifying the products.

Thus we perceive that this *séance* has been a very poor one; let us enliven it a little. In quitting it, we thought proper to reproach M. Fremy for having preserved for silicic acid the formula SiO_3. We said to him, "You are quite aware that with the numbers of molecules of silicium and oxygen given by this formula, it is absolutely impossible to constitute a molecule of silicic acid. You know that M. Marignac, of Geneva, Henry Rose, and others, have concluded, from very long researches, that the only possible formula is SiO_2." "This may be true, perhaps, and it is true; *but it is so inconvenient to change old habits.*" Nothing is, in fact, more convenient than error; nothing is often more austere than the truth. This is how routine goes on perpetuating errors, barring the access to true progress, even in the less exact sciences. How many thousands of chemical formulæ are more impossible than that of silicic acid; and how many thousands of errors proceed from the inkstands of chemists!

We learnt yesterday that the Lalande medal has been awarded by the Section of Astronomy to the Astronomer-Royal of the East Indies, M. Maclear, for the great work of triangulation, and the measurement of a meridian, that he has published.

We are now at the 19th February, and the Academy of Sciences has not yet held its annual public meeting for the distribution of prizes, which, according to the regulations, should take place, at the latest, in December. How does it happen that the learned bodies in France are so negligent?

NOTICES OF BOOKS.

A New Chemical Nomenclature. By S. D. Tillman. Albany (U.S.): C. Van Benthuysen and Sons. 1866.

We will try, as briefly as may be, to give an outline of the proposed scheme, but to understand it thoroughly the whole of Mr. Tillman's pamphlet should be carefully read. To quote from the context, the first words are, "The present seems very opportune for the introduction of a nomenclature which will more completely methodise the science of chemistry." "The nomenclature now presented is the result of an attempt to obviate the continual embarrassment attending the prosecution of chemical studies," and so the writer resorted to mnemonical methods. The present time is by far the best for the change, for "the meaning of the new notation being *definitely* fixed, while the nomenclature may be said to be still in the transition state, an atomic system of names, intended to supply the place *both of the notation and the old nomenclature*, is submitted for candid and critical examination." "This work was accomplished in a *true conservative* spirit, by building the new structure from old materials." The system is based on abbreviations of the universally received names of the chemical elements and symbols, with modifications found to be necessary. "The name of each chemical element given, not to its mass but to a minimum combining proportion called an atom. Thus the atom becomes the unit of measurement, and starting-point of the scale in each series of compounds." The atomic name of each *metal* consists of two syllables and ends with an m, but each "*metalloid's*" name terminates with a different consonant. In passing we must remark that Mr. Tillman uses the expressions "metalloid and atomoid." Thus the terminal consonant of fluorine is F, of bromine B, and of sulphur S, &c. The number of atoms of any element in a compound body is designated by the vowel immediately preceding its terminal consonant; the numerical value of the vowel advances with the alphabetical order: thus, A to U expresses 1 to 5, 5 to 10 by the same vowel with the full sound. For example, the iron in ferrous oxide is expressed as ferr-a-m, that in ferric oxide as ferr-e-m, F_5 = ferr-u-m, Fe_6 = ferr-ea-m (ā), Fe_7 = ferr-ee-m, Fe_8 = ferr-ei-m, Fe_9 = ferr-eo-m, Fe_{10} = ferr-eu-m. The long values of the vowels are taken for numbers above 10; thus, au = 16 (6 + 10) and oo = 18 (9 + 9). X is used with a vowel preceding it as an exponent, giving a progression; so 10 = ax, 20 = ex, 70 = eex, 80 = eix. Qu expresses the hundreds to, and including, 1000, by prefixing and suffixing. Thus, Mr. Tillman expresses 1080 by euqueix. We have shown how the metals are named, and the various atoms combining expressed, by this system, so we presume that an alloy of 1080 parts of zinc to 930 parts of copper would be zinceuqueixm-cupreoquixm; of course a more simple ratio exists in this case—*i.e.*, 108 : 93—but in a complex alloy such simplicity of ratio could not be attained. The non-metallic elements are named thus, fluoraf or af, sulp-a-s or as, phosph-a-p or ap. If the symbolic letter cannot be used, as the H in hydrogen (so getting hydrate), l is used to denote the lightest of substances, and d the densest, getting H = hydral or al, Cl = chlorad or ad, I being volatile, producing violet vapour, dav or av; oxygen is oxat, being the name of a single *atom*, or "the atom *par excellence*." An atom of selenium is selaz; it bears a strong resemblance to sulphas or as, expressed by similar sounds as, az.

These examples will suffice to show the author's drift. An additional character is used for each of the compounds of carbon and hydrogen. One example will suffice to show the most plausible use of this nomenclature.

3. The chromium atom, properly chromam, may be contracted to chram, which is especially convenient in denoting chromates.

Protoxide of chromium (chromous oxide), chramat.

Magnetic oxide of chromium (chromoso-chromic oxide), Cr_3O_4 = Chr-i-m-o-t.

Sesquioxide of chromium (chromic oxide), Cr_2O_3 = Chr-e-m-i-t.

Monochromate of sesquioxide of chromium, Cr_3O_6 = Chrimeat.

Bichromate of sesquioxide of chromium, Cr_4O_9 = Chromeot.

Neutral chromate of sesquioxide of chromium, Cr_5O_{12} = Chrumoit.

Acid chromate of sesquioxide of chromium, Cr_6O_{15} = Chreamyut.

Chromic acid, CrO_3 = Chramit.

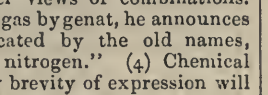
The author calls the residue of a molecule a torso; he thus writes phosphil, apt‴, from its atomicity being equal to the difference between the normal saturating power of its components; so hydroxyl H′O″ = alt′. Theoretically considering butyl as $(CH''_2\ CH''_2\ CH'_2\ CH'_2)$ + H, it becomes ochal′; ochet being butylic acid, acetic acid is achet, and amylic uchet, rutilic being euchet. "Apparent abnormal action, for instance, in the case

of I_2O_7, &c., may be accounted for by supposing an even number of atoms of oxygen, O_6, in alternately opposite polar conditions, to be united with I_2O." Great are the powers of theory! and certainly the applications of Kekulé's new views are almost limitless; for we are told that, in the case of the hydride of copper, cupramal, *a dyad metal plays the part of a monad.* It will supply a want of the mineralogist; for by this method Fe_3S_4, a magnetic iron pyrites with no systemic name, becomes on direct principles ferrimos, and another unnamed variety, Fe_7S_8, is ferreemeis. The author's enthusiasm, however, carries him a little too far. It may be all very well to write down bihydrochlorate of bibromoterchloronaphthaline ($C_{10}H_3Br_2Cl_3HCl$), or for $HIg_4H_4Cl_2N_2O_2$ tetramercuriotetrahydric-dioxidichlorodinitride; and the proposed substitutions hygomoledent and eurulebod are certainly shorter; but, if the composition is known to him, a practical chemist would express the formula at once, and so give more precise information with infinitely less effort; and there certainly would be no need for bearing any such name in mind. Equations also are abolished. "Williamson's original view of the constitution of ethers is expressed by the following:—Sodam-echalt with echal yields sodama and echalemat." The author gives the following reasons for the adoption of this scheme:—(1) It would be the chemist's shorthand—for example, CO_2 is pronounced with three syllables, and garet (*i.e.*, CO_2) with two, &c. (2) Chemical equations will be abolished, objected to on principle by some chemists. (3) Its use in conversation would soon correct many vulgar errors, and inculcate, by mere imitation and habit, clearer views of combinations. "When one designates laughing-gas by genat, he announces at once several facts not indicated by the old names, nitrous oxide or protoxide of nitrogen." (4) Chemical writers who are obliged to study brevity of expression will appreciate the saving of pen- and type-work by its use—*e.g.*, announcement of a late scientific achievement:—

Lossen has succeeded in replacing [an atom of hydrogen in ammonia by an atom of hydrogen and oxygen or hydroxyl; thus forming hydroxalamine].

Lossen has succeeded in replacing [al in ilan by alt; thus forming altelan].

Type.



It is, indeed, proper to say that the author has proved "the copiousness and capacity" of the new scheme, and we owe it to him in the barest justice to say that the scheme as a mnemonic scheme appears perfect; and that it is not more complex than such a scheme of necessity must be. The work has had bestowed upon it the greatest labour, thought, and knowledge; and, whether it be adopted or not, the thanks of the chemical world are due to Mr. Tillman, whatever its verdict may be, for giving them the opportunity of forming a correct judgment on the feasibility of any such scheme. But for our parts we think that although our ears might in time get accustomed to the seeming strangeness of the terms and their want of resemblance to anything to which we have been in the habit of attaching ideas—or, to go further, if in all future books the new name were added in italics, in lieu of the ordinary symbols which now involve the use of figures not often read easily, with the old name of the body—objections to its adoption would remain still. In the first place it is founded on shifting theories—*i.e.*, of complex organic nomenclature. 2nd. The tendencies of theoretical chemistry are in a totally different direction—to a mathematical, not mnemonic, expression of facts. 3rd. The chemistry of the old authors would be more than ever unavailable. 4th. The present rooted stage of chemistry will not allow a total revolution. 5th. A universal adoption, all but unattainable, is absolutely necessary for its success. 6th. Chemists would not only have to learn something fresh, but also unlearn all that they know, in as far as words express facts, not the facts themselves. 7th. It is, as the author states, a shorthand, and we should immediately have A.'s, B.'s, and C.'s systems also. Any one of these objections is in itself fatal to any scheme of the kind. We would also remind Mr. Tillman of what he says in allusion to the present changes in nomenclature now gaining ground. "No sweeping innovation which changes or perverts the meaning of old terms, rendering old and familiar works on chemistry comparatively worthless, and which tends to eradicate fundamental ideas, will be accepted by the present generation;" neither do we think it will be by any future generation.

NOTICES OF PATENTS.

1446. *Composition for Beautifying the Complexion.* J. Lewenberg, Upper Berkeley Street, Portman Square, London. (Not proceeded with.) Dated May 23, 1866.

The composition consists of—Pulverised egg-shells, one pound; calcined magnesia, two ounces; terra alba, one pound; marsh-mallow root, one pound; orris root, one pound; gum benzoin, half an ounce; rose-water, one pint; otto of rose, five drops; cascarilla root, quarter of an ounce. The proportions may be varied. A complexion beautified with the above concoction would be an interesting subject for exhibition at some scientific society.

1495. *Composition for Removing Incrustations and Preventing the Formation of the same in Steam-boilers.* G. Haseltine, Southampton Buildings, Chancery Lane, London. A communication. (Not proceeded with.) Dated May 29, 1866.

This is a mixture of baryta, sal ammoniac, sugar, and lye, which is to be added to the water in the boiler, when it not only prevents incrustation forming, but removes any that may already be there, and so considerably diminishes the risk of explosions. We confess we do not see the mode of action of this mixture.

1615. *The Purifying of Ammoniacal Liquor by an Improved Process, and the Application of such Purified Ammoniacal Liquor to the Purifying of Coal Gas.* G. D. Malam, Halifax, Yorkshire. (Not proceeded with.) Dated June 14, 1866.

This invention consists in the use of a "desulphurating scrubber," open at the top and partly filled with coke, into which a stream of ammoniacal liquid is caused to flow through a rose, and is met near the bottom by a strong current of air, which effectually desulphurates it. When coal gas is passed through the resulting liquid, the sulphuretted hydrogen and sulphur compounds are effectually removed.

1646. *Mode of Transmitting Messages by the Electric or Magnetic Telegraph.* F. J. Bolton, Bruton-street, London. Dated June 19, 1866.

This relates to the employment of a tabulated code of signals in telegraphy. Words and letters are expressed by groups of figures, which are telegraphed, as in the Morse system, by dots and dashes. The advantages claimed are a greater speed of transmission and less liability to error.

1628. *Method of Treating Permanent Inflammable Gases, whereby greater Heat is obtained therefrom.* B. F. Stevens, Henrietta Street, Covent Garden, London. A communication. Dated June 15, 1866.

In this invention steam is mixed with the gas just before burning, by which, it is stated, a much greater heat may be obtained.

1639. *Manufacture of Pigments.* J. E. T. Woods, Camberwell Grove, Surrey. Dated June 18, 1866.

This is a plan for utilising the lead deposited from lead

furnaces by treating it with common salt. A chloride of lead is thus formed which is suitable for making white pigments.

1707. *Preserving Animal Substances.* H. Medlock. Tavistock Square, London, and W. Bailey, Wolverhampton. Dated June 27, 1866.

This invention relates to the preservation of various animal substances by means of a solution of bisulphite of lime and gelatine, or bisulphite of lime and common salt.

Communicated by Mr. Vaughan, F.C.S., Patent Agent, 54, Chancery Lane, W. C.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

231. J. Greenshields, Glasgow, N.B., "An improved compound or combination of materials to be used for the production of illuminating gas."

241. C. E. Brooman, Fleet Street, "Improvements in the manufacture of soap." A communication from A. Phillipe and G. Forlier, Lyons, France.—Petition recorded January 29, 1867.

3232. T. Gray, Wandsworth, Surrey, "Improvements in the preparation of bleaching materials or compounds."—Dec. 7, 1866.

3300. E. Meldrum, Bathgate, Linlithgow, N. B., "Improvements in the manufacture of gas for illuminating and heating purposes."—Dec. 15, 1866.

242. E. de Nève, St. Mary-at-Hill, London, "Improvements in producing certain colours from aniline and coal tar."—Jan. 29, 1867.

Notices to Proceed.

2540. W. Hope and H. Browning, West Drayton, Middlesex, "An improved composition to be substituted for ordinary paints."—Petition recorded October 3, 1866.

2536. C. E. Brooman, Fleet Street, "The production and application of an imponderable fluid, together with the apparatus or means employed therein." A communication from M. Ziegler, Paris.

2696. G. W. Shinner, Strand, Middlesex, "Improvements in the means of, and apparatus for, utilising sewage matters and liquids."

2607. T. Outram, Grutland, near Halifax, Yorkshire, "Improvements in the manufacture of cast iron."—October 9, 1866.

2656. J. Dale and J. G. Dale, Manchester, "Improvement in sulphuring yarns and fabrics."—October 13, 1866.

2669. G. T. Bousfield, Loughborough-park, Brixton, Surrey, "Improvements in the manufacture of green and blue colouring matters." A communication from A. Poirrier and C. Chappat, jun., Rue d'Hauteville, Paris.

2671. A Swan, Kirkaldy, Fifeshire, "Improvements in, and in apparatus for, evaporating or recovering lees."—October 16, 1866.

2681. J. Slessor, Glasgow, N.B., "Improvements in distilling alcoholic spirits."

2683. J. Hamilton, Glasgow, N.B., "A new and improved fuel."

2686. C. A. Girard, Rue des Ecoles, Paris, "Improvements in the manufacture of blue colouring matter." Partly a communication from G. de Laire, Rue de Sèvres, Paris.—October 17, 1866.

2745. H. D. Plimsoll, Great Ormond-street, Middlesex, J. B. Davies, Gresham-street, London, and W. R. Dawson, Homerton, Middlesex, "Improvements in extracting metals from titaniferous iron, sand, or minerals containing metals."—October 24, 1866.

2756. H. Phillips, Clyst, Honiton, Exeter, "Improvements in the preparation of deodorising materials, and in the manufacture of gas."—October 25, 1866.

2773. J. Wagener, Wellclose-square, Middlesex, and G. J. Firmin, Millwall, Middlesex, "Improvements in sugar refining."—October 26, 1866.

3269. J. Baggs, High Holborn, Middlesex, "Improvements in the manufacture and treatment of hydrochloric and nitric acids."—December 13, 1866.

128. B. Lieton, Rue de Houblon, Brussels, "An improved composition to be employed in welding or soldering iron upon iron, steel upon steel, and iron upon steel."—January 18, 1867.

CORRESPONDENCE.

Standard Thermometers.

To the Editor of the Chemical News.

Sir,—Having had standard thermometers verified both at Kew and also by Mr. Glaisher, I can confidently assert that the difference between the zeros given in the two cases is very small indeed. The zero points of all thermometers, as a rule, rise in a month or so after the instruments are made. This rise varies generally between ½° and 2°. The bulbs of the best thermometers should be blown some months before the instruments are pointed. In this manner the greater part of the error may be avoided. Even after all due precautions have been taken, the thermometer should be either compared from time to time with another standard which has been repeatedly checked, or, when this cannot be done, its zero should be independently tested by means of melting ice. If boiling water should be used, the height of the barometer must be observed, and the influence of the atmospheric pressure taken into account. The use of boiling water is objectionable for the purpose of testing, as it has a tendency to permanently raise the zero of the instrument, even if it has been unchanged and correct before immersion. Those who possess old thermometers should ascertain their errors and then be careful of them, as from what has just been stated it follows that they will not be nearly so liable to further changes of their zeros as newly made instruments.

I am, &c. John Browning.

111, Minories.

To the Editor of the Chemical News.

Sir,—"A Subscriber" communicates in your last number an explanation by Mr. Pastorelli of the seemingly strange difference between a thermometer certified at Kew and another certified by Mr. Glaisher. It was not necessary, perhaps, to be at the trouble of consulting a manufacturer, as the right explanation is given in all good treatises on natural philosophy, and as it ought to be known to every one concerned with accurate thermometrical measurements, that newly made thermometers must not be graduated at once, owing to the slow contraction of the glass after having been exposed to the boiling heat of mercury. The most likely cause of the after-contraction is the one-sided pressure of the air. The bulb does not acquire, on cooling, its original size for some months. It is a universal practice with good scientific instrument-makers in Germany to keep their thermometers, after having made the mercury boil and sealed the tubes, for a whole twelvemonth before graduating them. Mr. Pastorelli explains the after-contraction of the glass by some circumstance in the manufacture, but this does not go to the root of the thing, because ever so long after the tubes have been manufactured and the bulbs blown, the after-contraction will appear whenever the instruments have been heated to the boiling point of mercury. Accordingly, every thermometer loses its accuracy for many months whenever it has served for the determination of higher temperatures, and there are very few thermometers in use in chemical laboratories that do not come under this head. An instrument, after adjustment, can only once be used for accurate determination of boiling points without readjustment, a circumstance very often lost sight of in chemical researches, and which explains, no doubt, many discrepancies between statements of different authors.

I am, &c. G. L.

South Shields.

Paper from Wood.

To the Editor of the Chemical News.

Sir,—In this last week's "Chemical News" I see a paragraph on how "To Recognise Wood-fibre in Paper," which speaks about "suspected" paper, as if wood-fibre was looked upon as an adulterator, as if it was illicit and added for the purpose of adulteration. Can you inform me if it is so? I hope not. I know a great deal of interest and trouble have been taken with it in this district, and that no small feeling of pride has been expressed at us being the first to start a factory for the production of wood-pulp for the fabrication of paper. The gentlemen composing the Company of Wood-pulp Manufacturers are the last to do a dishonourable act, and in their successful experiment to make pulp from old pit props into a state ready for the paper manufacturer, they were solely encouraged by their love of science and ambition to make paper from an abundant material in place of a scarce one. Had they any idea that they were acting dishonourably, nothing would give greater pain. The wood-pulp makes a capital brown paper for packing casks, &c.; in its fabrication it has rather too much water in it to be easily worked.

I am, &c. Inquirer.

[The word "suspected" was not employed in the sense in which "Inquirer" has taken it; nothing dishonourable was implied in the use of the word.—Ed. C. N.]

Discovery of Coal Gas.

To the Editor of the Chemical News.

Sir,—The following fact seems worthy of record, and may perhaps be a sufficient answer to the inquiry of "Rusticus" (page 72), "Who was the real discoverer of coal gas and its properties?"

The late Dr. Joseph Skey, who died a few months ago at a great age, told me a short time before his death, that he attended Dr. Priestley's chemical lectures in the New College at Hackney about the year 1793, and that, besides directing the attention of his class to the jets of inflammable gas sometimes produced in a coal fire, Dr. Priestley put some comminuted coal into the bowl of a tobacco-pipe, which he closed with clay, and, having put the bowl into a fire and produced a jet of gas, which he ignited, remarked to the class, "Now, gentlemen, I have no doubt that this will some time be turned to an important purpose." Dr. Skey said that he had the most clear remembrance possible of these circumstances.

Dr. Thomas Thomson, in his biographical account of Priestley ("Annals of Philosophy," i. p. 92, London, 1813), does not mention coal gas among the gaseous bodies produced and investigated by him. I am, &c.

James Yates.

Lauderdale House, Highgate, February 23.

Ozone.

To the Editor of the Chemical News.

Sir,—During the month of January, judging from the ozone tests, there were periods of ozone from the afternoon of the 5th to the 9th, and from the 20th to the 31st; periods of little or no ozone from the 1st to the morning of the 5th, and from the 10th to the 19th.

The period of ozone which commenced on the 20th of January still continues. Large quantities of ozone were present on the 7th, 23rd, 24th, 28th, 29th, and 31st; scarcely a trace on the 4th, 13th, 14th, and 18th.

I am, &c. R. C. C. L.

Sea Grove House, Bournemouth.

[Probably many of the discrepancies in the registration of ozone are due to the defective methods generally adopted. It would be doing good service if some experimentalist would devote attention to the improvement of the ordinary ozone papers, or to their replacement by some more trustworthy test.—Ed. *C. N.*]

Adulterated Gypsum.—German Yeast.

To the Editor of the Chemical News.

Sir,—Knowing gypsum to have been used extensively as a "drier" for manure, and also as a manure itself, perhaps it may be of service to those who use it to know that it often contains sulphate of baryta and other foreign matter—of course, I refer to gypsum in its ground state. I have known it to contain from 30 to 40 per cent. of $BaOSO_3$, &c. It would be an easy matter to point out the cause of this, but I have no desire at present to do so. It is for those who use it to say whether they will have a "mixture" or the genuine article. For my own part, I merely point out the fact.

I notice in No. 375 of the Chemical News a letter from a correspondent relating to German yeast. I have examined very large quantities of this yeast, and, if I except sand and similar bodies, I have in no case found any adulteration. The only thing I often noticed was putrefaction going on, barely visible to the naked eye, but with the aid of a common microscope it could be seen to great advantage, and took the form of a mass of corruption, which, in fact, it was. Has your correspondent examined the flour thoroughly? The days of alum and plaster are not yet over, and it is, in my opinion, much more likely to be the flour than the yeast that has been the cause of the illness he names. Your correspondent must be aware of the injurious effect alum, &c., has upon the system, especially in persons of weak constitution, when taken for a long time together in bread, &c.

I heard a short time ago of several cases of lead-poisoning which took place in America. It turned out that the bread eaten by the persons so poisoned contained lead, which was proved by analysis, and after a further search it was discovered that a miller in the neighbourhood from whom the flour had been obtained was in the habit of filling up the holes and fractures in his millstones with lead. Of course it followed that during the process of grinding the lead gradually wore away, and became mixed with the flour. Again, I have been told of millers filling up the holes in their millstones with alum and plaster of Paris, which, when used together, form a very hard composition. I will leave your readers to surmise what in all probability followed.

I am, &c. J. H. Swindells.

MISCELLANEOUS.

The Great Pyramid Weights and Measures.—The following prospectus announces the particulars of a work, by Professor Smyth, to be shortly published by Messrs. Edmonston and Douglas, Edinburgh, under the following title:—"Life and Work at the Great Pyramid, during the Months of January, February, March, and April, A.D. 1865; with a Discussion of the Facts ascertained," by C. Piazzi Smyth, F.R.SS.L. and E., Astronomer-Royal for Scotland. In three vols., each 500 pages. Vol. I. Journal of Proceedings. Vol. II. Numerical Observations. Vol. III. Discussion of Results. "A definite interpretation having been given, within the last few years, to some of the chief features in the Great Pyramid of Egypt, by the late John Taylor, of London, the monument has been recently submitted to very painstaking as well as extensive measurements; and with the effect of abundantly confirming his idea, that the Great Pyramid was intended by its primeval designer to memorialise a system of weights and measures for the use of all mankind. Its system is moreover found to be that on which not only the sacred Hebrew, but the hereditary weights and measures of modern European nations, of Saxon and Gothic origin, were founded in the early ages of the world. Though now much disordered by anomalous subdivisions which have since crept in, the whole arrangement can yet be brought back to its pristine simplicity and excellence,

in all these countries, by a reforming process only, and without recurring to the disadvantages of a radical revolution; leaving, moreover, in most cases, the standards and chief units employed by the mass of the people nearly unchanged as to absolute amount, but with their numerical relations much facilitated by decimal and quinary proportions, and their grand foundations in nature clearly exemplified. Thus, the Great Pyramid linear standard is founded on the length of the semi-axis of rotation of the world, being the one-ten-millionth thereof; and gives both the inch, and the length of the side of an acre, the same as the British to one-thousandth part; besides affording a cubit-length which comes between the ells of the old Prussian, Danish, and other important continental nations. The Pyramid weight and capacity standard is founded on the above linear standard, in conjunction with the specific gravity of the earth as a whole. Its pound, which is in nature five cubic inches of the earth's mean density, is almost identical with the British pound avoirdupois, and exceedingly close to most of the old pound-weights on the Continent. The Pyramid heat standard is the mean temperature of the whole surface of the earth; marks boiling water at 250°; the greatest density of water, at 10°; and the freezing of water, at 0°. In the Pyramid time standards, special respect is paid to the week of seven days; and throughout the building, there is such a constant and pervading protest against all idolatry, that the monument appears to have been originally, whatever it may have been used for afterwards, not so much an Egyptian, as a Hebrew-devised structure of the inspired period, and of the age of the early patriarchs."

Curious Electrical Phenomenon.—During the late intense frost the small river which waters the valley of Glenelg was, like others, covered with ice varying from six to nine inches in thickness. This, when partially dissolved by the thaw of last week, was broken up into large plates and rapidly carried to the sea, except where it met with obstacles that retarded its progress, where it remained piled up into great masses until the weight of the water accumulating behind forced it onwards. One of these obstacles consisted of a slight wire foot-bridge, which formed a communication between the two parts of the minister's glebe, which the river divides. This bridge was supported by four pairs of wooden posts standing in the bed of the stream, and against these a great quantity of the ice had been collected, until the water, obstructed by it, rose several feet above its natural level. Things were in this condition when, about 11 o'clock on the night of Wednesday, the 23rd, one of the maidservants at the manse, having occasion to cross the stream, and not being aware of the danger, went along the bridge, and had scarcely reached the bank when the whole structure was carried away, some of the wires being broken, and the others torn from their fastenings. Had the girl been a single minute later of crossing, her life would have been sacrificed, for she must either have been drowned in the swollen stream, or crushed to death by the heavy blocks of ice. On looking back to the bridge, the girl heard sounds emitted by the breaking wires above the roaring of the crashing ice, and saw a vivid flash of coloured light at every fracture of the wires This appearance might have been supposed to be due to the fright she was in at the time, had not a sister, who was in safety on the other side of the river, seen it likewise, and also a young man who was passing at the time along the public road, more than 200 yards from the spot. The phenomenon was probably caused by the wires being strongly charged with electricity, developed by the breaking up of the ice and the friction of the detached masses—separation of parts and friction being both known sources of electric action.—*Edinburgh Evening Courant.* [This phenomenon is evidently "Smatterer's" flash of lightning repeated: *vide* Chemical News, No. 372, p. 36.—Ed. C. N.]

Meetings for the Week.

Monday, March 4.

ANSWERS TO CORRESPONDENTS.

*** All *Editorial Communications* are to be addressed to the Editor, and *Advertisements* and *Business Communications* to the Publisher, at the Office, 1, Wine Office Court, Fleet Street, London, E.C. *Private* letters for the Editor must be so marked.

*** In publishing letters from our Correspondents we do not thereby adopt the views of the writers. Our intention to give both sides of a question will frequently oblige us to publish opinions with which we do not agree.

G. Lunge.—Received with thanks.

W. B.—We scarcely understand what our correspondent wants. Sulphuric acid will not dissolve carbonate of lead; it will convert it into an insoluble sulphate, and cannot be used as a test for its purity. Nitric acid would form a solution, and would probably answer your purpose.

A Reader.—Dr. Odling's lecture on Dialysis is in preparation, and will probably appear in our next number. If this does not give you the information you want, we must refer you to Professor Graham's original papers published in the *Philosophical Transactions.* Abstracts of these have appeared from time to time in the Chemical News.

Inquirer.—Your note is inserted in another part of the paper. The author of the articles has been unexpectedly called away from England. They will be shortly resumed, and continued without interruption.

Chinese Blue.—*Inquirer* wishes to know the proper method of making Chinese blue. One good plan is to grind equal weights of zaffre and potash with felspar equal to four times the weight of the mixture, fusing in a crucible and grinding the product to an impalpable powder.

Boronatrocalcite.—In the third note to this paper (last number, p. 86) it should have been stated that the old notation was used because the *new notation* is not yet very generally applied to mineralogical formulæ.

The Blowpipe.—*Dr. Muspratt* writes:—"Mr. David Forbes remarks: 'It will doubtless be admitted that in this country but very little attention has been paid to the use of the blowpipe.' This assertion I most certainly cannot endorse. It is now nearly twenty-four years since I presented, in an English form, Plattner's 'Probirkunst mit dem Löthrohre,' and since that time the blowpipe has been very generally employed, not only by the student, but by the expert in his laboratory and other operations. Several hundreds of pupils have been under me, and instruction 'upon the use and application of the blowpipe' has always been given. A gentleman, not long ago, wrote to me from Australia that he had found 'the blowpipe of much importance and use to him.' I have been engaged for some time with a fourth edition of the work, which may be published this year. Mr. Forbes states, 'Gas is not to be recommended, as it is difficult to obtain a good reducing flame when using it.' I have never experienced any difficulty." We regret that want of space compels us to omit several extracts from the preface and laudatory quotations from letters in favour of Dr. Muspratt's translation of "Plattner on the Blowpipe."

Received.—"Science Teacher;" A. B.; H. B.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On the Determination of the Quality of Silver prepared by different Methods, by J. Stas.

For the comparison of the silver produced and refined by different methods, I have made use of the mode of assaying in the moist way which is adopted in the Mint laboratories. I have taken care to increase tenfold the quantity of the material to be assayed.

To carry out this method with every possible condition of accuracy, I employed special arrangements that I have already mentioned briefly in my preceding work, and which I will now describe, with the suitable details, in accordance with the desire expressed by several chemists who have examined the apparatus.

The arrangement for the assay consists of three distinct parts—a reservoir containing a standard solution of chloride of sodium, a measurer, and an apparatus in which the titration is performed.

The volume of the reservoir was determined by means of the weight of the flask filled with dry air and with water. This volume at 10° was 6328·35 c.c.*

The measurer consists of a large pipette, surmounted by a long, almost capillary tube, subdivided into seventy equal spaces; it is furnished at the base with a slender tube, the diameter of the opening being 0·0015 m.

The capacity of the measurer, filled up to 0°, was determined by the diminution of weight caused by removing the water. This capacity was found to be 504,922 c.c. at 10° Centigrade.†

The measurer is permanently fixed in a glass vessel filled with water kept at a constant temperature; it is filled from the bottom by means of the liquids of the reservoir, led by a siphon provided with a glass tap, and terminated by an india-rubber tube, which fits on the narrow portion of the tube of the pipette. The measurer is provided at the top with a tap, which is opened when it is wished to fill it with liquid up to 0°, and which is kept closed when it is wished to leave the saline liquid in the vessel for it to take the temperature of the water bath that surrounds it.‡

Further to provide against variations of the temperature of the liquid, I waited, before making the determinations, until the temperature of the air in the dark room and of the water was sensibly the same.

To prepare the standard saline solution, I introduced into the reservoir 33·9653 grs. of pure salt. This weight represents 5·420 grs. of pure chloride, or 1009·844 c.c.—a volume double the capacity of the measurer at 10° Centigrade. According to my former experiments, 5·42078 grs. of pure salt should precipitate exactly 10·000 grs. of silver from the electrolysis of cyanide of silver and ammonium. I had therefore a latitude of nearly 0·001 gr. to make the assay—a more than sufficient quantity when we consider the great perfection of Gay-Lussac's method when it is properly applied.

The weighing of a previously determined quantity of chloride of sodium is an excessively delicate operation, and one it would be impossible to perform exactly if recourse were not had to an artifice. The following is that which I have employed, and to which I have always had recourse in analogous circumstances. After having calculated the weight in air§ of 33·9653 grs. of chloride of sodium, supposed to be weighed in a vacuum, which weight is equal to 33·9475 grs. I weighed, in a platinum crucible, this quantity broken into small fragments, and then submitted the crucible, enclosed in a second, to a dull red heat. Whilst the salt was still very hot, I introduced it, by means of platinum pliers, into a stoppered tube, which was also heated, and the weight of which had been determined. The tube having cooled, I took its weight, and supplied the few milligrammes wanting by weighing in an assay balance, as rapidly as possible, the quantity of chloride necessary to make up the total of the calculated weight of the chloride.

In the paragraph headed "On the Chloride of Sodium used in the Determinations, and Determination of the Proportional Relation between the Chloride and the Nitrate of Sodium," I show the method I used to procure the sodic chloride employed; I took every possible care to guarantee, as much as possible, its purity. I also give the means to which I had recourse to ascertain the quantity of foreign matter it contained, the weight of which amounted to from forty-seven to fifty millionths.‖

New Test for Cobalt in Solution, by William Skey, *Analyst to the Geological Survey of New Zealand.*

If to a solution of a salt of cobalt in tartaric or citric acid an excess of ammonia is added, the addition of ferricyanide of potassium will cause a very dark-red coloration in the solution.

So intense is the colour thus produced by the ferricyanide, that it will reveal the presence of cobalt in solution when all other tests fail, its delicacy being about four times greater than that of carbonate of ammonia.

A solution of cobalt prepared as indicated above, so as only to contain $\frac{1}{60000}$ part of cobalt, when placed in a $\frac{3}{4}$-inch test-tube, is very distinctly coloured by the addition of a soluble ferricyanide, and even when diluted down so as to contain but one part of colbalt in 400,000 parts of the liquid, the coloration is still distinctly visible in a bulk of a few ounces.

On the Action of Bismuth on Phosphoric Acid.—When a fragment of bismuth is thrown into glacial phosphoric acid infusion, the metal fuses to a bright globule, from which small flames appear. This phenomenon is sometimes so strong that particles of incandescent bismuth are thrown out of the vessel, forming a shower of sparks. There finally remains a spongy mass of bismuth, and a white powder, which is phosphate of bismuth. The flames which appear arise evidently from the phosphide of bismuth which would be formed, and which decomposes by giving up its phosphorus, or by forming phosphuretted hydrogen in contact with the water of constitution of the phosphoric hydrate.—*M. C. Braun, Zeitschrift für Chemie*, t. ii. p. 282.

† See the notes for the data used to determine the total capacity of the measurer and the capacity of the tube subdivided into seventy equal parts, note No. 4

‡ Thanks to the system of distribution of water in the town of Brussels, nothing is easier than to have, for eight or ten consecutive days, a current of water at a *constant temperature*. The greatest difference there is during the whole year in the temperature of the water does not even reach 4° Centigrade. During more than two months this temperature is very exactly 10° Centigrade.

§ I found the density of the chloride employed = 2·145; whence it results that, weighed in common air with platinum weights, it loses 0·0005366 gr. of its weight per grammo.

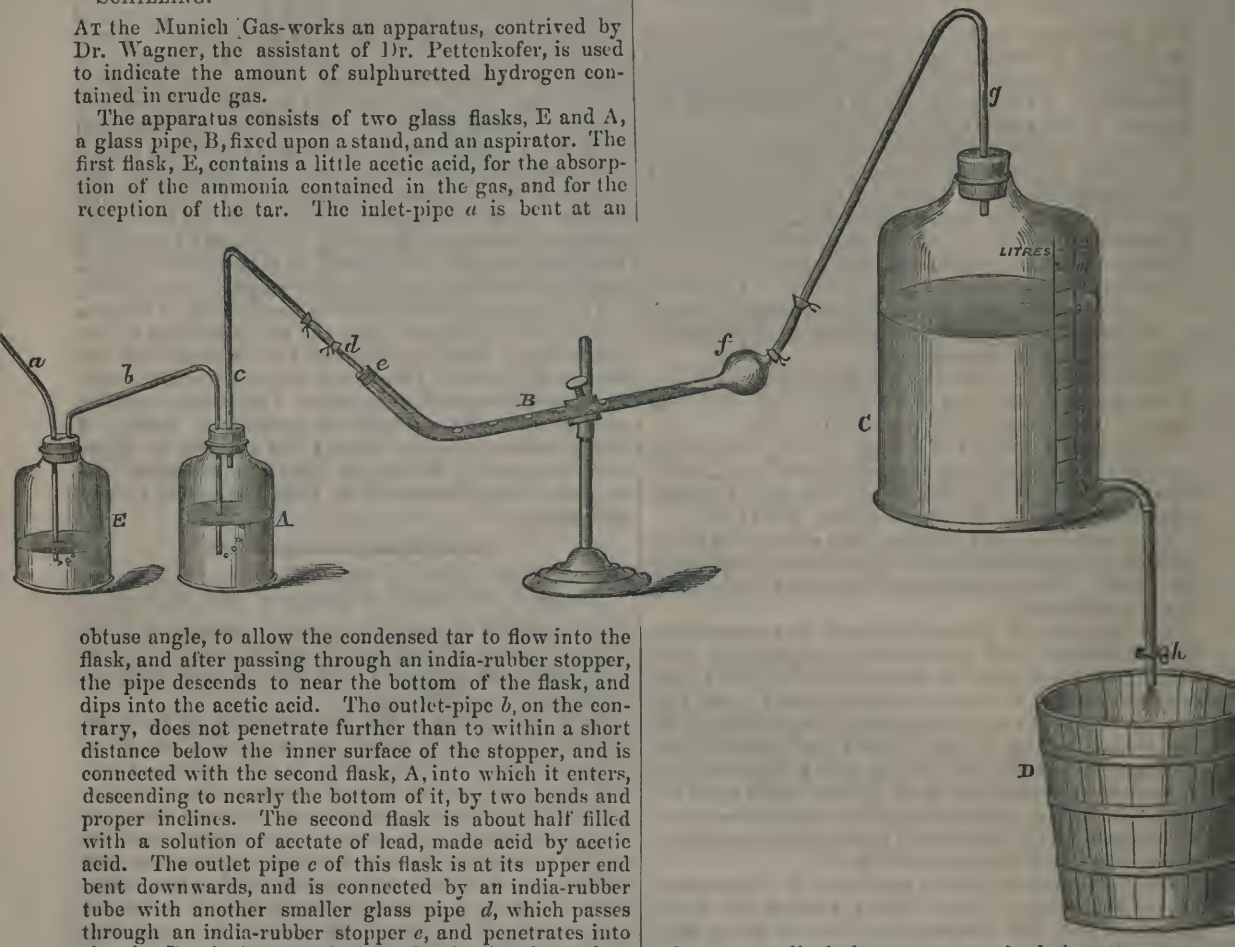
‖ By purifying, as much as possible, this chloride of sodium, and by also determining the quantity of foreign matter retained in spite of these purifications, my object was to use these new experiments for the determination of the proportional relation between silver and chloride of sodium, so as to deduce from these data the atomic weight of the silver and the molecular weight of the sodic chloride.

TECHNICAL CHEMISTRY.

Apparatus for Determining the Quantity of Sulphuretted Hydrogen contained in Crude Gas, by Dr.* Schilling.

At the Munich Gas-works an apparatus, contrived by Dr. Wagner, the assistant of Dr. Pettenkofer, is used to indicate the amount of sulphuretted hydrogen contained in crude gas.

The apparatus consists of two glass flasks, E and A, a glass pipe, B, fixed upon a stand, and an aspirator. The first flask, E, contains a little acetic acid, for the absorption of the ammonia contained in the gas, and for the reception of the tar. The inlet-pipe *a* is bent at an obtuse angle, to allow the condensed tar to flow into the flask, and after passing through an india-rubber stopper, the pipe descends to near the bottom of the flask, and dips into the acetic acid. The outlet-pipe *b*, on the contrary, does not penetrate further than to within a short distance below the inner surface of the stopper, and is connected with the second flask, A, into which it enters, descending to nearly the bottom of it, by two bends and proper inclines. The second flask is about half filled with a solution of acetate of lead, made acid by acetic acid. The outlet pipe *c* of this flask is at its upper end bent downwards, and is connected by an india-rubber tube with another smaller glass pipe *d*, which passes through an india-rubber stopper *e*, and penetrates into the pipe B to its lowest point, terminating in a fine end, so as to prevent the gas coming out otherwise than by a very narrow passage, and in small bubbles. The pipe B is about one metre long, and, as shown in the wood-cut, is also filled with a solution of acetate of lead. While the left extremity of this pipe is closed by the stopper *e*, its right has a globe *f* at the end for the deposit of any fluid that may have been carried over; and in continuation therewith is a glass tube, through which the gas takes its course to the aspirator C. This aspirator, which in this instance has a capacity of twelve litres, is closed by means of an india-rubber stopper, through which passes the inlet-pipe *g*, bent at the top, the extreme end of which, going downwards, is connected with the glass tube near the globe *f* by an india-rubber tube. At the bottom of the aspirator a small lateral pipe is inserted, with an india-rubber tube, the latter being provided with a pressure-cock (*Quetschhahn*), together with a thumb-screw, for the purpose of discharging the water.



When the apparatus is used, the gas is admitted by a connecting pipe between the hydraulic main and the condenser—nearest, however, to the former.

The cast-iron pipe is drilled at the upper part, and the ¾-inch outlet lead pipe is carried upwards—say, about 2 feet perpendicularly—to convey back into the cast-iron pipe a portion of the tar carried onward by the warm gas, but which soon becomes condensed. The lead pipe is then bent downwards, and carried about 10 feet in length to the experimental table, where it terminates with a stop-cock (*Schlanchhahn*). A short india-rubber tube is drawn over this cock so as to allow of its being connected afterwards with the apparatus. Before an experiment takes place gas is allowed to flow freely for at least half an hour through the supply pipe, in order that the inner surfaces of the same may become completely covered with tar, thus insuring that the lead of the pipe does not decompose the sulphuretted hydrogen of the gas.

After filling both the flasks and the pipe in the manner before described with the absorbing fluids, and completely filling the aspirator with water, and making tight all the connexions of the apparatus, the water is allowed, by opening the pressure cock *h*, to flow out of the aspirator until atmospheric air in the form of bubbles is sucked up by the apparatus, and until the level of the water corresponds exactly with one of the

* *Journal of Gas-lighting*, translated from the *Journal für Gasbeleuchtung*.

marked lines of the aspirator. The cock *h* is then again shut for a short time, and the loose end of the india-rubber tube fastened to the supply pipe is then drawn over the glass pipe *a*. It is of course premised that the pressure of the gas in the supply pipe is = o, as is the case in establishments where exhausters are used. Upon the connexion being restored between the apparatus and the supply pipe, the pressure cock is again slightly opened, and the gas allowed to pass gently—say about 20 litres per hour—until the water level in the aspirator has descended to the line marked 1. The flow of the gas is kept up as uniformly as possible by the regulating screw of the pressure cock. As we allow at our experiments from 40 to 50 litres to pass each time, it is necessary that the above experiment should be repeated several times. The pressure cock and the cock of the supply pipe being again shut, the stopper of the aspirator is loosened, the aspirator again filled with water, and the entire operation repeated in the manner above described.

Where no exhausters exist, and where there is a pressure of several inches in the (gas) supply pipe, no aspirators are required, but a gas-meter is used instead.

In the first flask, E, filled with acetic acid, is collected the greater portion of the tar; no absorption of sulphuretted hydrogen takes place here, as the crude gas enters it at a high temperature. In the second flask, A, and also very slightly in the pipe B, a black precipitate is formed, composed partly of sulphuret of lead, partly of tar. The latter, however, is apt to carry down with it a considerable quantity of the solution of lead employed. In order to bring the precipitate thus formed into a ponderable condition, it is first filtered, then well washed, and dried at a temperature of about 100° C., and put into a small porcelain dish. Fuming nitric acid is then repeatedly poured over it, also at a temperature of about 100° C., and this is continued until the black mass has become quite white. When this has taken place, the residue of the nitric acid is driven off by evaporation at 100°. By the above operation the sulphuret of lead is converted into sulphate of lead, the tar is destroyed, and the lead carried down by the tar is changed into nitrate of lead. It is known that sulphate of lead is insoluble in water; nitrate of lead, on the contrary, is readily soluble. For this reason the white mass is washed with water in a porcelain dish, and separated by filtration from the insoluble sulphate of lead. The latter, after being properly washed and dried, is heated in a crucible and weighed as $PbOSO_3$, from which the sulphuretted hydrogen is estimated according to the formula—

$$PbOSO_3 : HS = 151{\cdot}5 : 17.$$

The Theory and Working of Blast Furnaces, by Wm. Crossley, *F.C.S., Manager Ormesby Iron Works.**

(Continued from page 98.)

Ebelmen gives the following as the result of his analysis of the gases escaping from a furnace at Clerval in France :—

	Per cent. by volume.
Nitrogen	57·22
Carbonic acid	12·01
Carbonic oxide	24·65
Marsh gas	·93
Hydrogen	5·19
	100·00

* Communicated by the author.

Taking only the carbonic acid and carbonic oxide, we find they are in the proportion of 12·01 of the former to 24·65 of the latter in every 36·66 parts of the mixture, or 32·75 parts of carbonic acid to 67·25 carbonic oxide in every 100 measures.

The material used in the production of the above was as follows :—

295 parts Iron ore
115 ,, Charcoal
15 ,, Limestone

and the approximate composition of the mixed iron ore and limestone—

	Per cent.
Water	12·50
Carbonate of lime	21·00
Sesquioxide of iron	39·20
Oxide of manganese	·70
Silica	20·00
Alumina	6·60
	100·00
Metallic iron	27·00 per cent.

And on the assumption that the whole of the oxygen in the iron ore oxidised its equivalent of carbonic oxide to carbonic acid, and that this carbonic acid is not again reduced, we should have a gas containing the carbonic acid and carbonic oxide in the following proportions :—

Carbonic acid	33·72
,, oxide	66·58

and Ebelmen found, as already stated—

Carbonic acid	32·75
,, oxide	67·25

The nearness of the above figures to each other would certainly seem to bear out the theory I have advanced, and I may here state that from some original investigations, as well as from the analysis of the gas escaping from Ormesby furnaces, I have had the above results confirmed. I should here state that in the above calculation 15 per cent. has been deducted from the charcoal, for ash, volatile matter, and moisture.

The above results, then, seem to indicate (excuse me for stating it so frequently) that the reduction of iron takes place in a much higher and cooler part of the furnace than is generally supposed, and that the change of carbonic oxide into carbonic acid, and its subsequent reduction into carbonic oxide again, does not take place; carbonic acid once formed in the reducing region is never again converted into carbonic oxide, but leaves the furnace as carbonic acid.

If the above views are correct, they also explain another process adopted in the manufacture of iron which has always been enveloped in some amount of mystery—viz., the theory of the calcination of ironstone. There cannot be the slightest doubt that the beneficial results obtained by the calcination of ironstone are greater than would be obtained by a mere decrease in weight and the previous evolution of volatile matter by exposure to intense heat; for in calcining, besides a loss of about 20 per cent. which the ironstone suffers, the protoxide of iron absorbs oxygen and becomes converted into a higher oxide, called the peroxide—that is, every 36 parts of oxide of iron, containing 8 parts of oxygen, absorb 4 more parts, and the oxygen thus absorbed, as well as that originally contained in the ore, by oxidising their equivalent of carbonic oxide, thus assist in heating and preparing the material for the further changes it has to undergo in the lower part of the furnace.

If the above is not the case, I would ask how it can

be explained that the calcination of limestone does not give equally beneficial results with those obtained from the calcination of ironstone, when by this operation limestone loses about 42 per cent. of its weight, where ironstone only loses about 20 per cent. Taking these facts into consideration, then, I think we are justified in stating that calcination is productive of good as much from the fact that it gives oxygen to the iron as from its effect in driving off the volatile matter.

(To be continued.)

FOREIGN SCIENCE.

(From our own Correspondent.)

M. Clemandot, director of the crystal glass manufacture of Clichy, near Paris, has patented a new process of silicatising pottery, founded upon the property possessed by the alkaline silicates of dissolving easily in water, and combining with argil by the aid of heat. This can be effected either by the application of a superficial coating, or by the impregnation of the clay itself. In the first case, the clay, after being entirely or partially burned, is coated with a solution of the alkaline silicate, applied by means of a brush as often as is necessary to render the coating impermeable; it is then burned at a temperature high enough to determine the fusion of the silicates and their combination with the pottery. In the second case, the pottery-ware is steeped in a solution of the silicate, which it imbibes on account of its porosity; subjected afterwards to the action of heat, the silicate forms an impervious material. These processes, so simple, have the advantage of dispensing with the use of the oxide of lead which forms the habitual base of the glazing, which is corrosible by the weakest acids.

M. Bourne has succeeded in removing from india-rubber its disagreeable odour by operating as follows:— The articles of india-rubber are placed in an enclosed vessel, they are surrounded with charcoal dust, and submitted to a temperature of 60° to 70° C. during several hours; they are then taken out, and the charcoal is removed from them. They are thus not the least changed in form even in the most delicate details, and the odour is found to have completely disappeared. India-rubber thus treated can be placed in contact with food of any sort without risk of communicating an unpleasant odour. For heating the india-rubber we can employ either hot water, steam, or the heat even of the vulcanisation, so that the objects quit the vulcaniser completely inodorous.

M. Cordure has exceeded his predecessors by making use of the affinity of silver for lead in order to separate the latter from argentiferous lead ore. When the argentiferous lead is melted, a small quantity of zinc is added, and after an energetic brushing the mixture is allowed to repose. The alloy of zinc and silver, being lighter than lead, rises to the surface, and as it is less fusible, it cools sooner. By watching the proper moment the silver can be skimmed off, united with zinc and a small quantity of lead. The zinc and the lead are separated by remelting the skimmed mass, and oxidising by means of a current of hot air or superheated steam, and treating afterwards with hydrochloric acid; the residue is submitted to cupellation. Nothing hinders the chloride from being utilised in its actual state, or being transformed into carbonate of zinc.

To vitrify cast iron by the process of M. Paris and others, a very fusible green colour in powder is dusted over it, and the whole is afterwards submitted to a red heat in an oven. M. Balloutrey, on the contrary, places the surface to be covered in contact with the elements which produce ordinary white glass, and heats it to the point of vitrification. The iron combines, in oxidising, with the silicic acid of the glass, and the union is complete between the latter and the metal. The protective coating can be rendered as thin or as thick as may be required, but in giving a thin layer the unequal dilatations of the metals have less effect upon the separation of the metals. Experiments are being made for protecting, on this principle, the iron-plating of vessels from corrosion. They are being carried on by the French Government.

M. Jules Roth, of the Industrial Society of Mulhouse, has made some interesting researches upon the composition of raw tartrates of Alsatia and their adulteration. The tartrates of commerce coming from the wine coopers, where they are found deposited at the bottom of the casks, generally contain from 81 to 85 per cent. of white tartrate.

These tartars, in the rough, without admixture of foreign substances of the above percentage, are generally sold by druggists. The percentage in the rough tartrates of merchants and those used by dyers is very far from the normal quantity, which proves that the merchants mix them with other substances, in order to be able to sell them at a cheaper rate. For this purpose the dried lees of wine are principally made use of; these are used in great quantities in the south of France, at Bordeaux, and in the Charente, and which only contain from 6 to 7 per cent. of pure tartrate. The process of M. Dosaye, employed by M. Roth, is founded on the saturation or the neutralisation of the tartaric acid by means of a standard solution of crystallised soda, marking 14° of Decrosilles. The more alcohol the wines contain, the less tartar they form. It is the acid wines, such as those of Alsatia, the Rhine, &c., that furnish most.

Electric Light.—In a few days the electric light of the Alliance Company will be installed on board the *Prince Jerome*, the yacht of H.I.H. the Prince Napoleon; and M. Georgette Dubuisson, the excellent captain, will proceed at once with some most interesting experiments on the light. It is not to illuminate the vessel itself, but, on the contrary, to light up other objects, such as a coast or a vessel, for the sake of attack or defence; ships at full speed or in station can thus be kept free of all danger of collision, and, in action, the object to be hit can be illuminated. The regulator of the charcoal ends is to be established on board the above yacht on the principle of M. Leon Foucault, so admirably constructed by M. Duboscq. This instrument has the advantage of not only having a regular movement when in a vertical position, but also burning with the same precision inclined at any angle, so as to be independent of the pitching or rolling of the vessel at sea. The apparatus placed behind the lamp, and which, hiding the light from the deck of the vessel, projects it in parallel rays on a given spot, has been constructed by M. Sautter. It is a first essay; it is not, however, the night-glass by our friend, Dr. Jules Guyot, and which is composed of two substances placed in juxtaposition—one containing the combination of mirrors necessary for the projection in space of a pencil of parallel rays, the other a complete telescope serving to observe the point or object that the parallel rays illuminate at a distance. Since the essential data for this new problem and its complete solution, the moment has arrived for constructing perfect instruments which will leave nothing to be desired. Recourse, perhaps, must be had to the condenser, of which M. d'Henry, of Lille, has given the ingenious theory, and which increases a hundredfold the light, already so intense, of the electric focus. However late in the field of practical adaptation, the electric light once established on board a vessel will become a necessary adjunct to the marine and transport service.

The illumination of this same light for railways, in the stations and the approaches thereto, tunnels, curves, &c., has been the order of the day, and the subject of deep study for some weeks past. M. Jacquemin, director, along with the engineer of the East Railway of France assisted at experiments carried on at the works of the

Alliance Company at the Rue du Puits Artésien, Passy. They were very successful, and we have reason to expect the best results. Let those gentlemen allow us to place the focus close to the ground, so as to illuminate it and not the atmosphere.

Lastly, the question has been mooted of substituting in electric gilding and silvering, as also in galvanoplastic, of round bosses where the simple element cannot be made use of, the current of magneto-electric machines. M. Christofle and M. Bouillet have perceived that nitrous acid disengaged by the Bunsen piles were not sufficiently drawn off by the chimneys which were constructed for the purpose at great expense, and became every day more dangerous; so they have resolved to make use of electricity engendered mechanically. They made a first essay at the works of the Alliance Company, and they have ordered two machines of four discs. In the establishment of M. Lenoir, 88, Rue Popincourt, a machine of this kind has been established, which promises great success. We may add that the magneto-electric machine of Mr. Wilde has been employed also in the celebrated workshops of Messrs. Elkington, of Manchester. The current is able to deposit a pound of copper per hour, and economy and salubrity are assured. F. Moigno.

The following list of medals granted by the Société d'Encouragement completes the awards mentioned last week:—

Silver Medals.—Belou, caloric engine; Blot, statuettes in terra cotta; Bon, imitations of precious stones; Chaudun, improved cartridges; Courcier, self-acting lubricator; Guesnier, grey cast iron covered with white iron; Guiot, thermoscopic barometers; Havrez, lixiviating apparatus; Journaux-Leblond, sewing machines; Lacroix, vitrifiable colours; Mathieu, straw hats; Vidard, railway carriages.

Bronze Medals.—Beillard, door closing; Baudu, safety key; Cabel, mosaic flooring; Dumas, hypsogoniometer; Gauthier et Duchamps, sewing machines; Lecornu and Roserau, new cremonas; Masson, apparatus for measuring rations of oats for horses; Molard, locomotive with rotatory engine; Parraud (a poor working man, who came in his blouse, and was most warmly applauded), wooden taps for wine barrels and casks; Peraux, method of dividing a circle; Sanguet, longimeter; Thomas, compound compasses; Valasse, safety guard for small arms.

PROCEEDINGS OF SOCIETIES.

ROYAL INSTITUTION OF GREAT BRITAIN.

Friday, January 25, 1867.

Sir Henry Holland, *Bart., M.D., D.C.L., F.R.S., President, in the Chair.*

A paper, by William Odling, M.B., F.R.S., was read, "*On Mr. Graham's Recent Discoveries on the Diffusion of Gases.*"

I.

When atmospheric air is separated from a vacuous or partially vacuous space by a septum, partition, or bag of india-rubber, some air passes through the septum into the originally vacuous space.

This space may be conveniently maintained vacuous, and any air passing into it be simultaneously withdrawn and delivered for examination, by means of Sprengel's exhauster.

Whereas atmospheric air consists of about 21 per cent. of oxygen and 79 per cent. of nitrogen, the air transmitted through india-rubber into a vacuous space is found to contain about 40 per cent. of oxygen and 60 per cent. of nitrogen, and to have the property of re-inflaming a glowing splinter.

A transmission, therefore, takes place through the rubber septum of both constituents of the atmosphere, but there is a greater proportionate transmission of its oxygen than of its nitrogen.

Single or unmixed gases, similarly separated from a vacuous space by a septum of india-rubber, penetrate the rubber and enter the vacuous space with the following relative velocities:—

Nitrogen	1
Marsh-gas	2·15
Oxygen	2·55
Hydrogen	5·50
Carbonic acid	13·58

From these velocities the observed passage of mixed oxygen and nitrogen gases through india-rubber is deducible by calculation; and, conversely, the separate velocities of oxygen and nitrogen are deducible from the transmission-results obtained with atmospheric air:—

Oxygen	21 × 2·55	= 53·55	.	40·4
Nitrogen.	79 × 1	= 79·0	.	59·6
		132·55		100·0

The constituent gases of atmospheric air not only pass through an india-rubber septum into a vacuous space, but also into a space containing some other gas, such as hydrogen or carbonic acid, and at the relative velocities with which they enter a vacuous space; but the conditions of the experiment then become more complicated.

In the case of an india-rubber balloon filled with carbonic acid, for instance, not only are atmospheric oxygen and nitrogen gases continually entering the balloon, but carbonic acid gas is continually and very rapidly escaping from it.

Throughout the vacuum experiment, the conditions remain constant, the hyperoxygenised air being withdrawn as fast as transmitted; but in the balloon experiment the oxygen is gradually accumulating within the balloon, whereby the conditions are constantly varying.

Eventually, by the rapid escape of carbonic acid, the proportion or pressure of oxygen in the internal mixture comes to exceed that in the external air; whereupon a reverse transmission through the balloon, of the excess of oxygen into the external air, at once begins.

II.

When ordinary coal-gas is separated from a vacuous space by a septum, partition, or tube of platinum, some gas passes through the platinum septum into the originally vacuous space, as soon as, but not until, the metal is raised to the temperature of ignition.

Whereas coal-gas is a variable mixture of marsh-gas and hydrogen with several other gases and vapours, containing on the average about 45 per cent. of marsh gas and 40 per cent. of hydrogen, the gas transmitted through ignited platinum is found to consist exclusively of hydrogen.

A transmission, therefore, of only one, and that not the most abundant, of the many constituents of coal-gas, takes place into the originally vacuous space through a septum of ignited platinum.

So that while the nitrogen of the air is transmitted through a septum of india-rubber in a much smaller ratio than its oxygen, the other constituents of coal-gas are transmitted through a septum of ignited platinum in an infinitely smaller ratio than is its hydrogen.

Experimenting with single or unmixed gases, the quantity of hydrogen transmitted through a septum of ignited platinum into a vacuous space amounted to over 100 cubic centimetres in half-an-hour; whereas, under the same conditions, the quantity transmitted of oxygen, nitrogen, marsh-gas, carbonic acid, and some other gases, did not amount to ·01 cubic centimetre in half-an-hour.

Further, the transmission of hydrogen through a septum of ignited platinum, as of various gases through a septum of india-rubber, takes place into a volume of some other gas as well as into a vacuum, but with a similar complication of results.

What is the nature of these transmissions of gas through india-rubber and ignited platinum respectively? Are the phenomena in the two cases similar or dissimilar to each other; and with what class of actions are they one or both associated?

III.

By a sufficient degree of pressure, gases may be forced through the minute channels of a porous septum; or, in other words, may pass through such a septum by *transpiration*.

But transpiration takes place only through obvious channels or pores, from which india-rubber and platinum are entirely free.

Again, transpiration through a porous septum takes place only in the direction of the preponderating total pressure; but the transmission of gas through india-rubber and ignited platinum, from one gaseous space into another, can take place in the opposite direction to that of the total pressure, and in both directions at the same time, by a sort of interchange of gases through the septum.

Moreover, the composition of a mixed gas, such as atmospheric air or coal-gas, is not altered by mere transpiration; whereas the composition of these mixed gases is greatly altered by their transmissions through india-rubber and ignited platinum respectively.

Lastly, every gas and every mixture of gases has its own special velocity of transpiration, irrelative to any other property of the gas, and irreducible to any general law. These rates are altogether different from the observed rates of transmission of the same gases through india-rubber and ignited platinum, thus:—

Oxygen	1·00
Nitrogen	·87
Carbonic acid	·73
Marsh-gas	·55
Hydrogen	·44

From these differences in the character of the phenomena, as well as from another important difference hereafter to be mentioned, it is clear that the transmission of various gases through india-rubber, and of hydrogen through platinum, is not due to transpiration.

IV.

As the channels of a porous septum become more and more minute, their resistance to the bodily transmission of gas becomes greater and greater, and the quantity of gas forced through them less and less, until at length the septum becomes absolutely impermeable to transpiration, under the particular pressure.

But such a septum, of which the individual capillary channels are so small as to offer a greater resistance, or friction, to the passage of gas through them than the available pressure can overcome, may nevertheless present a considerable aggregate of interspace, through which the proper diffusive movement of gases, due to their innate molecular mobility, may take place freely.

When any volume of gas is allowed access to a vacuous space, or to an additional gaseous space, it gradually diffuses itself throughout the space afforded it, at a rate inversely proportionate for each gas to the square root of its specific gravity.

In so far as the aggregate area of interspace available for diffusion is greatly diminished, by the introduction of a porous non-transpiring septum between the diffusing gas and the additional space afforded it, so is the amount of diffusion within a given time proportionably diminished; but in no other respect does the septum appear to take any part in the action; it neither promotes nor retards the diffusion, but simply allows it to take place in proportion to the aggregate area of the interspace which it affords.

The experimental determination by means of Bunsen's diffusionometer of the relative diffusion-velocities of different gases through a thin plate of compressed graphite —a septum without obvious pores and quite impermeable to transpiration—has given numbers which are almost identical with the reciprocals of the square roots of the specific gravities of the several gases:—

Hydrogen	3·80
Marsh-gas	1·34
Nitrogen	1·01
Oxygen	·95
Carbonic acid	·81

Interdiffusion of different gases takes place in proportion to their respective diffusion-velocities. Thus with air and hydrogen separated from each other by a graphite septum, for every 1 volume of air which passes into the hydrogen-space, 3·8 volumes of hydrogen pass into the air-space.

Mixed gases also diffuse away from one another according to their respective diffusion-velocities. As a result of even the small superior diffusiveness of nitrogen over that of oxygen, the proportion of oxygen in atmospheric air has been increased from 21 to 24·5 per cent., by the diffusion of nitrogen away from it, during its conveyance through several lengths of porous tobacco-pipe enclosed in a vacuous space.

The acts of gas-diffusion through porous septa and of gas-transmission through india-rubber and ignited platinum resemble each other in several points. They both take place through septa free from obvious pores; they both take place as well in the direction as against the direction of the preponderating pressure, and also in opposite directions at the same time by a sort of interchange; and they both effect an alteration in the composition of any mixed gas subjected to their operations.

But they differ altogether from one another in the relative velocities with which the gas-movements in each case are effected—the transmissions of gas through india-rubber and ignited platinum being at special rates, while the diffusions of gas through porous septa are inversely as the square roots of the specific gravities of the particular gases.

Thus, the specific gravity of nitrogen being somewhat less than that of oxygen, its rate of diffusion is accordingly somewhat higher, in the proportion of 101 to 95. Hence, if the passage of air through the rubber septum were due to diffusion, the transmitted air should be rather richer in nitrogen and poorer in oxygen than the original air; whereas the transmitted air is actually found to be very much richer in oxygen and poorer in nitrogen than the original air.

Again, hydrogen having a far lower specific gravity than marsh-gas, its diffusion rate is very much higher, in the ratio of 380 to 134. Hence, taking the proportion of marsh-gas to hydrogen in coal-gas as 1 to 1, and it is usually rather greater, if the passage of coal-gas through ignited platinum were due to diffusion, for every 380 volumes of hydrogen transmitted there should be 134 volumes of marsh-gas: but in reality no marsh-gas whatever is transmitted; so that neither with the rubber septum nor with the platinum septum are the results due to diffusion.

It is rare to have phenomena of diffusion undisturbed by phenomena of transpiration, or phenomena of transpiration undisturbed by phenomena of diffusion; but since the alteration in the composition of a mixed gas by its passage through a transpiring-diffusing septum is effected solely by diffusion, the results obtained with the rubber and platinum septa are not due to joint transpiration-diffusion.

V.

A septum may be quite free from pores of any kind or degree of minuteness, and so far be absolutely impermeable to the passage of gas through it in the form of gas, but may nevertheless permit a considerable transmission of certain gases by their prior solution or *liquefaction* in the substance of the septum.

The merest film of water, as of a soap-bubble for instance, is quite impermeable to gas as gas; but allows the ready transmission of a soluble gas, such as ammonia, through it, by reason of a prior solution or liquefaction of the ammonia in the film of water.

The film of water may be replaced by a moist membrane

of any degree of thinness or thickness, with a similar result.

In this case the phenomenon consists in a solution of the gas in the moist material of the septum—in a diffusion of the liquefied gas as a liquid through the thickness of the septum—in an evaporation of the liquefied gas from the remote surface of the septum—and, lastly, in a diffusion of the evaporated gas into the adjoining space.

Of the many circumstances affecting the final result, the influence of the solubility of the gas in the liquid of the septum would so far predominate over all other influences as to allow of their being left out of consideration. Whence it may be affirmed that the transmission of any gas through a film of liquid, or a moist septum, will be found proportionate to the solubility of the gas in the liquid.

But gases are absorbable not only by liquids, but also by certain solids, and especially by charcoal.

The gases absorbed by charcoal are probably liquefied in the charcoal; at any rate, the more absorbable of them occupy a bulk considerably less than if reduced to the liquid state by pressure.

All charcoal is more or less porous; but its absorption of gases is not proportionate to, or a mere physical effect of, its porosity; since other similarly porous substances do not manifest the same absorptive power, and since the absorbability by charcoal of any gas is as special a property of that gas as is its solubility in water or alcohol.

The transmission of an absorbable gas through a septum of compact charcoal, such as the cocoa-nut charcoal used by Mr. Hunter, of Belfast, which absorbs about $\frac{8}{10}$ths of its volume of mercury, and 111 times its volume of ammonia, would take place in two ways.

A portion of the gas would pass through the fine pores of the charcoal as gas, by diffusion, at a rate inversely proportionate to the square root of its specific gravity; while another portion would become liquefied in the charcoal by capillary condensation, pass through the charcoal as a liquid, and evaporate from the other side, just as would a gas liquefied by solution in a moist membrane; and it is conceivable that, in some compact forms of charcoal, the transmission of gas by gaseous diffusion might be inappreciable as compared with its transmission by liquefaction and evaporation.

VI.

Whereas the mere passage of gas through a transpiring or diffusing septum takes place in thorough independence of the nature of the material of the septum, in these last considered actions the transmission takes place by virtue of a sort of chemical affinity between the gas and the material of the septum—the selective absorption of the gas by the septum being a necessary antecedent of its transmission; whence it may be said that the gas is transmitted because it is first absorbed.

Is, then, the transmission of oxygen, &c., through india-rubber, and of hydrogen through ignited platinum, effected by a process at all allied to that of gas-liquefaction by solution or capillary condensation?

That septa of india-rubber and platinum differ from merely diffusive and transpiring septa, in effecting or allowing a selective transmission of certain gases through them, is evident; but do they first exert a selective or, in other words, a *chemical absorption* of these particular gases?

Experiment answers that they do; oxygen proving to be more than twice as absorbable by india-rubber as by water, and hydrogen proving to be fully three times as absorbable by wrought platinum as by charcoal.

The statements of fact and interpretation contained in this abstract are based upon the investigations of Mr. Graham, spread over a long period of years; and especially upon the investigations described in his more recent memoirs "On the Molecular Mobility of Gases" (*Phil. Trans.*, 1863), and "On the Absorption and Dialytic Separation of Gases by Colloid Septa" (*Phil. Trans.*, 1866).

MANCHESTER LITERARY AND PHILOSOPHICAL SOCIETY.

Ordinary Meeting, February 19, 1867.

J. P. Joule, *LL.D., F.R.S., Vice-President, in the Chair.*

Mr. Sidebotham inquired whether any member was acquainted with the particulars of a remarkable discovery in connexion with the conversion of dynamical into electrical force by M. Siemens and Dr. Wheatstone, a brief notice of which appeared in the *Athenæum* of February 16.

Mr. Wilde said that he happened to be present at the meeting of the Royal Society on the 14th inst. when M. Siemens' interesting paper "*On the Conversion of Dynamical into Electrical Force, without the Aid of Permanent Magnetism*," was read. The apparatus used in his experiments, and exhibited at the meeting, consisted of two electro-magnets, coiled with long and thin wires, and between the poles of these electro-magnets an armature, also coiled with long and thin wires, was made to revolve rapidly by means of pulleys.

When a voltaic battery was connected with the wires of the electro-magnet for a few moments, and afterwards disconnected, the residual or permanent magnetism of the electro-magnets was sufficiently strong to generate a feeble current of electricity in the wire of the revolving armature. The feeble current thus generated was then transmitted through the coils of its own exciting electro-magnet, instead of the current from the battery, and by the mutual action and reaction of the electro-magnet and the armature upon each other, the magnetism of the machine could be exalted to such a degree as to require the application of very considerable power to drive the apparatus.

That this increase of magnetism was attended by an increase of dynamic electricity in the wires surrounding the armature and electro-magnet was manifest from the brilliancy of the spark at the commutator and the increased deflection of a galvanometer needle placed within the influence of the electro-magnetic circuit; but the quantity of electricity was not sufficient to ignite wires, and was comparatively small in proportion to the mechanical force expended in producing it.

The apparatus used by Dr. Wheatstone in his experiments, which was also shown in operation at the meeting, was very similar in construction, and identical in principle, with that of Siemens, though each of these experimentalists appears to have worked out his results independently.

Instead of the long and thin wire used by Siemens in his machine, Wheatstone employed coils of thicker wires, and the wire on the electro-magnet was of the same diameter, and about eight times the length of that on the armature. The coils of the electro-magnet had consequently about eight times the resistance of the armature circuit. In this arrangement, the wire surrounding the armature being the generating circuit, it follows from a well-known property of the electric circuit, that the amount of dynamic or useful effect which the current is capable of exerting when the resistance of the coils of the electro-magnets is in circuit, is about one-ninth of the total amount which the armature coil is capable of evolving when the electro-magnet is excited to the same degree by a separate battery or other electro-motor.

This peculiarity of the machine was made evident by Dr. Wheatstone in a very striking manner by means of the following well-devised experiment:—Two branch wires were led off from the extremities of the armature coil, and when the electro-magnet was fully excited the free ends of the branch wires were bridged across by means of a fine platinum wire about nine inches in length, which wire immediately became white-hot, and as suddenly ceased to be visibly hot until contact with the branch wires had been broken for a short time and afterwards re-established.

This momentary ignition of the platinum wire appeared to Mr. Wilde to be due to the diversion of the greater portion of the current generated by the armature into the

new channel or short circuit established by the platinum wire through the armature coils, before the high degree of magnetism which had been maintained in the electro-magnet by the full current from the armature had been reduced by the loss of a portion of the current so diverted.

The results obtained by Siemens and Wheatstone are undoubtedly very interesting from a scientific point of view, but, practically, the exciting of the electro-magnet by the current from the armature used in connexion with it produces results very inferior to what are obtained from similar machines, the electro-magnets of which are excited by a separate source of electricity of small power, as, in the latter case, the full force of the current generated by the armature coil is available for the performance of external work.

Mr. Wilde having himself, some time ago, made some experiments similar to those of M. Siemens and Dr. Wheatstone, came to the conclusion that, in the present state of our electrical knowledge, the difficulty of utilising the current from the armature after it had passed through the coils of the electro-magnet was insuperable; as it is absolutely necessary that the coils of the electro-magnets of electro-magnetic machines, when excited by intermittent currents, should be of considerable length, in order that they may acquire and retain a charge of electricity or magnetism, as has been shown by Drs. Henry and Faraday in their experiments on the induction of a current upon itself. On the other hand, for the production of powerful electro-dynamic effects, it is necessary that the wire of the armature coil should be comparatively short and thick. Hence the incompatibility of the armature and electro-magnetic circuits, when exalted dynamic effects, outside the machine, are required.

It is not a little interesting to observe how, in the progress of physical science, the same train of reasoning is often pursued by several individuals having no communication with one another. In the present instance, it would appear that the "augmentation of the power of a magnet by induction currents produced thereby, and reacting upon the magnet itself." has also suggested itself to other experimentalists besides M. Siemens and Dr. Wheatstone. In a letter published in the *Engineer* of July 20, 1866, p. 42, the writer (Mr. J. Murray) says:—"The description in recent numbers of the *Engineer* of Mr. Wilde's admirable improvements in the magneto-electric machine induces me to point out, if you will permit it through your columns, a variety of the principles embodied in his machine, which is so obvious that it cannot fail to be hit upon by some inventor before long."

It is briefly this:—"Whereas Mr. Wilde, beginning with an ordinary magneto-electric machine, uses the current obtained from it to charge a powerful electro-magnet, and from this obtains a second and more powerful current, which, used in like manner, produces one still more intense, I, using only a single machine, pass the current obtained from its armatures through wires coiled round the permanent magnets, in such a direction as to intensify their magnetism, which, in its turn, reacts upon the armatures and intensifies the current.

"It is obvious that the amount of mechanical force which can thus be converted into electricity is only limited by the capacity of the iron for magnetism; just as the power of a steam engine is only limited by the capacity of the boiler for absorbing heat."

Mr. Wilde has also received a letter on the subject of his recent experiments in magnetism from Mr. Moses G. Farmer, of Salem, Mass., United States, dated November 9, 1866, in which he says that he had obtained an increase of 31 per cent. in the power of a magneto-electric machine by transmitting the current from the armature through coils of wire surrounding pieces of soft iron forming the prolonged extremities of the permanent magnets of the machine. Mr. Farmer, in the same letter, adds:—'I have built a small machine in which a current from the thermo-battery excites the electro-magnet of your machine to start it, and after the machine is in action a branch from the current of the magnets passes through its own electro-magnet, and this supplies the magnetism required. It is not exactly like a person standing in a basket and trying to lift himself—because the electricity proceeds from the conversion of the mechanical energy, which must be continually supplied. Neither can it in any wise be likened to the various schemes for producing perpetual motion; but depends on the principle that the actual energy of the mechanical force, conjointly with the potential energy of the magnet, can develope a greater amount of potential energy than is originally resident in the magnet, or, in other words, it is a method of converting part of the actual energy of the prime mover into the potential energy of magnetism."

ACADEMY OF SCIENCES.

February 25, 1867.

(From our own Correspondent.)

On the subject of the assertions of M. Hermann, of Berlin, relative to the dangers of protoxide of nitrogen (laughing gas), Mr. Preterre (American dentist, of 28, Boulevard des Italiens) addressed to the Academy the following letter:—"In presence, on the one hand, of these assertions, and, on the other, of the considerable number of anæsthetics daily made use of in France by me, and also in America on a more vast scale, I trespass again on the indulgence of the Academy to request that the Commission named for this purpose will be kind enough to attend during my experiments, when I shall place myself completely at their disposal." The perfect innocuousness of the protoxide of nitrogen used by M. Preterre is accounted for by the fact that he prepares it the night before, and, after having well passed it through water, he leaves it for many hours in contact with water. Under these conditions the trioxide of nitrogen or nitrous acid, which always accompanies the protoxide, combines with the oxygen of the water, and forms nitric acid, soluble in the water, leaving the nitrous oxide gas absolutely pure.

Messrs. Bussy and Buignet presented the second part of their memoir "*On the Changes of Temperature produced by the Mixture of Liquids of Different Natures.*" The following are the very important conclusions arrived at:—1. In all the cases under examination, with one sole exception, the calorific capacity of the mixture is a little superior to the mean capacity of the elements. 2. By a singular opposition, the liquids for which the increase of bulk is the most considerable are exactly those which develope most heat at the moment of their union, such as ether and chloroform, alcohol and water, sulphuric acid and water. Meanwhile the only instance hitherto noticed of a diminution of bulk is the mixture of *chloroform* and *sulphide of carbon*, at the same time the decrease of temperature taking place at the moment of the union. 3. Independently of the loss of heat resulting from the changes of volume, there exists a cause which produces alone an absorption of heat—an absorption which can be sometimes equal, and even superior, to the heat given out by the combination of the liquids. This cause, perhaps, may proceed from the separation of the homogeneous particles necessary for the *diffusion* of the liquids.

M. Fizeau communicated the result of his researches on the dilatation of crystals. He experimented this time upon several series of salts presenting a great analogy with each other—such as the chlorides, bromides, and iodides—hoping that this analogy would be manifested by the manner in which crystals are influenced by the action of heat. His previsions are in general confirmed, and in the course of his studies he has discovered an anomaly quite singular, and which constitutes a veritable discovery. While the coefficient of dilatation of all the chlorides, bromides, iodides, is positive in the same manner as it is

for all substances experimented upon, up to the present day the coefficient of dilatation of the iodide of silver is alone negative, so that this salt, instead of dilating, really contracts. Raised to a temperature of 40° C., the coefficient is $-0{\cdot}00000139$. This coefficient is, besides, variable with the temperature and the direction in the interior of the crystal. In the direction in which the contraction is greatest, parallel to the axis, it is the $\frac{1}{7000}$ part for 100°, about a tenth of the dilatation of mercury.

General Morin presented and described an electric thermometrical register for marking in an automatic manner, every quarter of an hour, the variations of temperature in an enclosed spot or in the open air, and which was very serviceable during his experiments on ventilation. Our readers are already aware that some excellent apparatus have been invented and put in use—for example, that of the reverend Father Secchi—for registering the variations of temperature, not only intermittently, but continuously.

M. Dupré, of Rennes, Ile-et-Vilaine, has recently adapted with success the mechanical theory of heat to the transmission of sound.

M. J. M. Gougoin has addressed, on the subject of the gas-couple of Mr. Grove, a note in which he arrives at conclusions in perfect conformity with those of M. Schönbein. Mr. Grove supposes that it is indispensable for each of the electrodes of platinum of his gas-couple to be simultaneously in contact with one of the gases and with the liquid placed underneath. M. Gougoin states, on the contrary, that the action of the platinum does not take place except on the gases already below, and that the gas-receivers should only be considered as reservoirs to maintain in a state of saturation the solutions they cover. The electro-motive force of the gas-couple varies curiously with the state of the platinum wire. Its action is increased, as M. Matteucci remarked, by heating the elements in the flame of a spirit-lamp some instants before employing it. In the most favourable conditions, the electro-motive force of the gas-couple constructed with platinum wires not platinised scarcely exceeds 155, taking as unity the electro-motive force of a thermo-electric couple of bismuth and copper, the two solderings of which are maintained at the temperature of 0° and 100° C. The electro-motive force of the couple of Daniell is represented by 193, and that of the couple of Volta by 178, at the moment of being set at work.

NOTICES OF PATENTS.

Communicated by Mr. Vaughan, F.C.S., Patent Agent, 54, Chancery Lane, W. C.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

279. O. Monnet-Laverpilière, Rue Notre Dame des Victoires, Paris, "A new agricultural fecundating agent."

285. W. E. Newton, Chancery-lane, "An improved process for obtaining metals from their ores." A communication from J. N. Wyckoff, Brooklyn, New York, U.S.A.—Petition recorded Feb. 1, 1867.

325. J. Wright and T. Cobley, Copthall-court, Throgmorton-street, London, "Improvements in the treatment of ores of lead for the purpose of obtaining salts and colours of the same."—Feb. 6, 1867.

337. J. Graham, Warrington, Lancashire, "Improvements in the manufacture of spelter from zinc ashes and refuses obtained when coating iron with zinc."—February 6, 1867.

379. W. Clark, Chancery Lane, "Improvements in preserving animal or vegetable matters, whether fluid or solid, in a wholesome and edible condition, without material loss or change of their natural flavour." A communication from L. H. Spear, Braintree, Orange, Vermont, U. S. A.—February 9, 1867.

CORRESPONDENCE.

Determination of Phosphates.

To the Editor of the Chemical News.

Sir,—With regard to the difference which a correspondent finds between the analysis of one chemist as compared with that of another in the amount of soluble phosphate reported, it has occurred to me that, supposing the determination to have been made in the ordinary manner, both chemists, when they found they had a first-class manure under examination, would be careful to redissolve the phosphate after burning, and again precipitate so as to get it perfectly free from adhering salts, but when the manure contained a smaller proportion of phosphate one analyst might trust to "washing well" to cleanse the once precipitated phosphate, whilst the other would treat it as he would if as large as the amount obtained from a better manure. The thorough washing of phosphates being a tedious and difficult operation, the little time expended in redissolving and again precipitating them, if not quicker, has the advantage of giving greater accuracy to the analysis.

I am, &c.

Geo. Hopwood.

Manchester.

Science Teachers.

To the Editor of the Chemical News.

Sir,—The following has just been communicated to teachers of science classes in connexion with the Science and Art Department:—

"My Lords consider the subject of examinations for certificates as teachers of science. They determine that, for the future, all candidates who obtain a first or a second class in the May examinations shall be deemed qualified to earn payments on results, according to the rules of the Science Directory, and that the special examinations in November for teachers' certificates be dispensed with."

As this change is a most important one, and likely to materially affect both teachers and pupils of science classes, I beg you will allow me space for a few remarks thereon. It has hitherto been the practice of the Department to hold two distinct examinations in science during the year—the one in November of candidates for teachers' certificates, the other of pupils of science classes in May. And it is so very obvious that this distinction should be preserved, in order that the attainments of intending teachers should be more severely tested than those of their future pupils, that the discontinuance of the November examinations is calculated to arouse, in all persons connected with the spread of scientific education, feelings of astonishment and disgust.

It might be thought that, in bringing about such a change, some cogent reasons for the step would have been vouchsafed, but there is not the ghost of an intimation of the grounds on which "my Lords" have been induced to come to their decision; and it may be safely predicted that, amongst all persons interested in science teaching, there will be but one opinion on the subject, and that not very complimentary to the judgment and common sense of the South Kensington authorities. On looking over some of the most recent examination papers, it cannot but be admitted that those for candidates for teachers' certificates differ very little, as regards the amount of knowledge required to answer the questions, from those set for advanced pupils of science classes in the May examinations; and this may have suggested to the authorities the desirability of fusing the two examinations into one, and thus, while diminishing the labours of the officials, reducing the expenses of the Department. But if economy had been the object it might have been attained in other and less objectionable ways—for instance, by discontinuing the allowance to successful candidates in November

for railway travelling and personal expenses, and letting each one pay his own expenses.

It was a feature in the November examinations that candidates were tested as to their practical acquaintance with the subject they desired to teach; and although little perhaps was required, yet the correct performance of that little was some sort of guarantee that the candidate knew how to "handle his tools." Under the new regulation, it will be impossible to test a candidate's practical skill, and the result must be to raise up a class of teachers who may be able to get a second-class or even a first-class pupil's prize as the result of their examination on paper, but who, owing to the absurd regulations in respect to science classes, may have never so much as worked with a microscope, dissected a plant, or handled a test-tube. It is such a palpable absurdity that a student in a science class should, with the limited time and advantages at his disposal, after a couple of years' study of any particular science, be considered capable of setting up as its expounder, that one can hardly help regarding those who encourage this state of things as ignorant not only of the essential qualifications of a science teacher, but of the very nature of science itself.

If "my Lords" had been really anxious for the spread of scientific knowledge amongst the artisan classes, they should have preserved the distinction between the November and May examinations, raised the qualifications of candidates for teachers' certificates, and demanded a more thorough practical knowledge of the various subjects. Instead of this, the effect of the recent regulation will be to increase largely the number of inexperienced, unpractical teachers, without adding to the strength of the science classes; and the present staff of teachers, finding the payments from the Department for small classes will not remunerate them for their time and outlay for apparatus, &c., will be compelled to give up science teaching in disgust. So utterly absurd does the whole thing appear—so ill-advised and ill-considered—that I cannot but regard it as calculated, if not directly intended, to create a prejudice against the teaching of scientific subjects; and it will cause no surprise in me if the next we hear from South Kensington be that Government aid to science classes is to be altogether abolished. I am, &c.

A Science Teacher.

Woolwich, February 23.

Chemical Notices from Foreign Sources.

Monobasic Carbon Acids.—1. Acetic acid (C = 12, O = 8).—A. Geuther refers to his former paper on this subject in "Reports of Royal Society, Göttingen," 1863, p. 281, and proceeds to inquire if the constitution of acetic acid is expressed by the formula

$$CH_2,CO_2 \left\{ \begin{matrix} HO \\ HO, \end{matrix} \right.$$

and similarly for its derivatives, whether the molecule of water contained in its salts is or is not replaceable by metallic oxides. If it is not, then the acid carbon compounds naturally split into two groups, one group in which the water is only partly, the other in which it is wholly, replaceable by bases. To the former group belong acetic acid, its homologues, and, indeed, most other acid carbon compounds; to the latter group belong oxalic and carbonic acids and the derivatives of carbonic oxide (croconic acid, &c.). To get an answer to this question, Geuther acted upon ethylic acetate with sodium, and obtained, among other products, the sodium salt of ethyldiacetic acid, or ethylenedimethelencecarbic acid (äthylendimethylencarbonsäure), carbic acid = formic acid. The formula of this salt is

$$\left. \begin{matrix} CH_2,CO_2 \\ CH_2,CO_2 \\ C_2H_4 \end{matrix} \right\} \begin{matrix} HO \\ NaO. \end{matrix}$$

It is decomposed by water, giving alcohol, acetone, sodic carbonate, and carbonic anhydride. The best mode of preparing ethyldiacetic acid is by adding strong acetic acid to the sodium salt, extracting with ether, and distilling the extract. The pure acid boils at 180·8°, has sp. gr. 1·03 at + 5°, and does not redden dry litmus. Its most characteristic reaction is that with neutral ferric chloride, with which it gives, even in dilute solutions, a splendid dark cherry-red colour. Its barium and copper salts are described. Its salts generally resemble in solubility those of acetic acid; the silver salt decomposes under water very rapidly, even in the dark. The examination of the ethyl and methyl compounds, boiling respectively at 198° corr. and 186·8° corr., confirmed the author in his view of the constitution of the sodium salt. Ammonia reacts on ethylic ethyldiacetate, giving rise to two amides, the relation between which remains the subject for further research.

Geuther thinks it not impossible that ethyldiacetic acid is sometimes present in the urine of diabetic subjects.

If sodic ethyldiacetate is heated in a stream of carbonic acid, an acid provisionally named dehydracetic $C_8H_8O_8$ is obtained; its hydrogen, barium, sodium, and calcium salts were prepared. Dehydracetic acid is crystallisable, melts at 108·5°—109°, boils at 269·6° corr., dissolves freely in boiling water and ether, sparingly in cold water.

A severe criticism of a paper "*On the Action of Sodium on Valerianate of Ethyl*," by J. A. Wanklyn,* and some caustic remarks on the—as the author conceives—tardy recognition in England of the first account of this research with reference to "*Notes of Researches on the Synthesis of Ethers*," by Frankland and Duppa,† conclude the paper.—(*Chem. Centralblatt*, N. S. xi. 785.)

Niobium.—Marc Delafontaine has studied the binoxide of niobium Nb_2O_4, and the protoxide Nb_2O_2; the former is obtained by intensely heating niobic acid in a current of hydrogen. It is an indifferent body of so great stability that it is more probable that it is the oxide of a radicle niobyle Nb_2O_2 than a niobic niobate; this oxide has been known as hyponiobium. The protoxide resulting from the action of sodium on sodic oxyfluoniobate has, until now, been described as niobium. Although resisting most reagents, it combines with chlorine, forming an oxychloride which, with the oxyfluoride and oxysulphide, establish its true composition. The metal niobium, therefore, remains yet to be isolated.—(*Arch. Sc. Phys. Nat.*, N. S., xxvii. 167.)

Di-isopropyl and Amyl-isopropyl (C = 12).—C. Schorlemmer has prepared and examined these bodies, and finds that, like other members of the marsh-gas series, they are highly indifferent to sulphuric and nitric acids, and are therefore easily purified. Di-isopropyl, boiling at 58°, forms with chlorine in the cold a body $C_6H_{13}Cl$ having the greatest resemblance to hexylic chloride, and boiling at 122°. Amyl-isopropyl boils at 110°, and forms with chlorine a body resembling octylic chloride, and boiling at 165°. These two hydrocarbons differ fundamentally in their reactions with chlorine in presence of iodine.—(*Zeitsch. Chem.*, N. S., iii. 1.)

Hippuric Acid in Animal Organisms.—Dr. Meissner and C. Shepard, in the examination of blood and other animal fluids for hippuric and benzoic acids, where the presence of succinic acid is suspected, rely on the solubility in absolute alcohol of the alkali and calcium salts of hippuric and benzoic acids, the corresponding salts of succinic acid being insoluble. Normal blood—at least that of herbivora—always contains succinic acid, but never contains benzoic or hippuric acids. The hippuric acid found in the urine of herbivora is first produced in the kidneys, and is not simply separated by them from the blood. There is no

* *Journ. Ch. Soc.*, N. S., ii. 371.

† *Annal. Ch. Pharm.*, cxxxv. 217.

clue to the nitrogenised substance which in the body of the animal becomes converted into hippuric acid. Whatever it may be, it certainly is not urea.

The observation of Lautemann, that quinic acid becomes converted in the human body into hippuric acid, is fully confirmed.

Wöhler's early observation, that the administration to human subjects of succinic acid causes an increase both of the normal quantity of that acid in the urine, and also of the carbonic acid, without influencing the excretion of hippuric acid, is also fully corroborated.

With respect to the source of the hippuric acid found in the urine of herbivora, the authors have succeeded in identifying it, partly at least, with the cuticular substance described by Mohl as a continuous membrane covering the higher plants on those surfaces which are freely exposed to the air, and by Mulder as an envelope of the epidermal cells. Its chemical relations are very imperfectly known, but it is rather more digestible than cellulose. The authors agree with Henneberg, Stohmann, and Rautenberg, who found that the addition to straw and hay, which provoke an abundant excretion of hippuric acid, of an easily digestible, non-nitrogenous substance, as sugar, causes an increase in the quantity of urea, and a decrease in that of hippuric acid. The quantity of hippuric acid excreted depends, moreover, both on the general vital conditions of the animal and on the individual; thus, a horse at work under like conditions excretes more than when it is at rest. An elevated temperature appears to increase the excretion of succinic acid and urea, and to diminish that of hippuric acid; but the individual peculiarities of the beast have, in this case, much influence.

There appears to be an intimate connexion between the presence in the urine of calcic carbonate and hippuric acid. When the latter is abundant the urine is strongly alkaline and turbid with calcic carbonate.

The authors leave open the question whether a diet which in herbivora is provocative of hippuric acid has the same effect upon man.—(*Zeitsch. Chem.*, N. S., iii. 2.)

Uric and Kynurenic Acids.—G. Meissner considers that the excretion of kynurenic acid in dogs is dependent on the particular individual experimented on. To separate uric and kynurenic acids, Meissner boils with water and barytic carbonate, filters, crystallises the barytic kynurenate from the filtrate, and separates the uric acid from the residue on the filter by means of chlorhydric acid. Kynurenic acid appears wholly or partially to obliterate the murexide reaction for uric acid.—(*Zeitsch. Chem.*, N. S., iii. 9.)

Cumol (C = 12; O = 16).—Schaper finds that nitro-cumol crystallises in long yellowish needles, fusing at 71° and boiling without decomposition at 265°. Cumidine (from nitro-cumol *viâ* tin and chlorhydric acid) crystallises from its hot aqueous solution in long silky needles easily soluble in alcohol, fusing at 62°. The sulphate and oxalate are crystallisable. Paranitroxylylic acid $C_9H_9(NO_2)O_2$ is obtained by oxidising nitro-cumol with chromic acid. It is crystallisable, easily soluble in alcohol and hot water, difficultly so in cold water, and fuses at 195°. The barium and calcium salts are crystallisable and easily soluble in water. The ethyl ether crystallises from alcohol and is easily fusible. Schaper is engaged on other oxidation products of cumol, and thinks that he has already obtained xylylic acid, fusing at 125°.—(*Zeitsch. Chem.*, N. S., iii. 12.)

Photometer.—Professor Schönbein suggests the use of a solution of cyanin as a photometer. He finds that the depth of colour which it takes on exposure to light varies in proportion to the strength of the light, and that the phenomenon occurs also in vacuo.—(*Arch. Sc. Phys. Nat.*, N. S., xxvii. 149.)

Ozone.—Professor Schönbein has studied the formation of hydric peroxide by the slow oxidation of organic matter, and finds that in most cases the co-operation of light is necessary. The action resembles the slow oxidation of phosphorus, in so far as the oxygen is split up into ozone and antozone. The antozone (positive oxygen) always remains combined either with water or with the matter undergoing oxidation, forming an organic antozonide, whilst the ozone (negative oxygen) is set free only when the substance undergoing oxidation is in the state of vapour. There are two classes of organic bodies—those which give hydric peroxide and an organic antozonide, and those which give only the latter. Some organic antozonides are very permanent—as, for instance, fossil amber.—(*Arch. Sc. Phys. Nat.*, N. S., xxvii. 149.)

Cupric Peroxide.—W. Schmid prepares this body by shaking a very dilute solution of cupric sulphate with hydrated or anhydrous manganic binoxide.—(*Journ. prakt. Chem.* xcviii. 130.)

MISCELLANEOUS.

Royal Society.—On Saturday, March 2, the President of the Royal Society (General Sabine) gave a *soirée* at Burlington House, which was numerously attended. The most striking scientific novelty was Wilde's large magneto-machine, which was exhibited in the lower library, and worked by a steam-engine. During the arrival of the guests the electric light produced was directed upon the court-yard, which it brilliantly illuminated, its direct rays almost equalling those of the sun. The same machine also fused seven feet of thick iron wire, and with the quantity armature bars of iron and platinum a quarter of an inch in diameter were at once liquefied. The new principle in magneto-electricity, discovered simultaneously by Mr. Siemens and Professor Wheatstone, was exemplified in two machines exhibited by those gentlemen, and which attracted much attention. Not the least curious object shown was a long gas flame, which, at the slightest sound of a harsh or hissing character, immediately contracted to one half of its former height. It beat perfect time to a tune played by a musical box, and was even affected by the ticking of a watch, while tearing a piece of paper threw it into a violent commotion. Among other things interesting to chemists we noticed a very complete set of thallium salts exhibited by Messrs. Hopkin and Williams, which are now about to be forwarded to the Paris Exhibition.

Blake's Stone-Breaker.—We would call the attention of manufacturing chemists and those of our readers who may be interested in mining works to a notice in our advertisement columns of Blake's patent stone-breaker, the merits of which, we think, would, if sufficiently known, cause its more general adoption. We have had the opportunity of seeing one of these machines in operation at the Welsh Gold-Mining Company's Works, near Dolgelly, and certainly nothing could be more striking than the facility with which it crushed the hardest masses of quartz and granite. Could not something of the sort be employed on the stones for the metropolitan roads, the final crushing of which is now left to be done by the wheels of carriages and the feet of horses, to the great injury of both?

First Prosecution under the Alkali Act of 1863.—On Monday last, at the St. Helen's County Court, before Mr. Judge Blair, Mr. Price, solicitor, of Manchester, applied to the judge that his costs in the case of Messrs. Leather and Co., of the Bridgewater Smelting Company, who have lately become alkali manufacturers, might be allowed. It appears that this firm was lately summoned for having allowed a large quantity of muriatic acid gas to escape into the atmosphere, contrary to the said Act, and the firm had paid the full penalty of 50*l.* into court.

Paper Pipes and Cisterns.—Chemical works suffer in common with private individuals from the effects of severe frost, in the bursting of the pipes and cisterns from which they derive their supply of water. It may interest chemists and others to know that pipes and cisterns may be made of a material which effectually resists the frost, and, strange as it may appear, the material employed is paper. The late severe frost afforded abundant opportunity for confirming the opinion expressed by Mr. Szerelmey, that the materials which he employs render paper a perfect non-conductor, and that as such it will resist the action of frost. In the open yard of his factory at the Albion Works, near Battersea Bridge, there was, during the past winter, one large brick tank containing several tons of water, the ice upon which was several inches thick. By the side of this was another, made of paper boards, the water in which was not the least frozen. Some iron pipes which supplied water to the boiler of the engine-house from the large cistern burst in several places on the thawing of the frozen water which they contained. Some paper pipes, on the other hand, filled with water, and which have been exposed in snow on the ground, perfectly kept the water from freezing. In a model house, or hut, made of paper, and which is erected on the open space, some water in bowls and pails did not freeze, though outside the building there were large masses of ice. The encaustic colours with which the exterior of the paper house had been painted, and which had also been applied to brick, iron, stone, timber, and a variety of other materials, retained their peculiar brightness and brilliancy throughout the whole period of the continued frost. These very practical and severe tests would seem to establish very fully the value of the processes. If water does not freeze under the conditions referred to, a very large amount of that discomfort and annoyance so generally experienced at the time of frost and thaw would be arrested by the substitution of these paper pipes and cisterns for the ordinary ones of lead or iron.—*Railway News.*

Pulverisation of Liquid Fuel.—Captain Schpakovski, Professor at the Russian Military College of Paul, has recently made some very curious experiments on certain applications of the "powder of liquids," or, in other words, on water, alcohol, turpentine, naphtha, and other substances, in a very finely divided condition. The advantage obtained by such minute subdivision is the obtaining complete combustion of the whole of the carbon contained in the liquid. The Captain has constructed a peculiar lamp, which may be regarded as the typical instrument of his system. The flame of this lamp, fed by turpentine, rises to the extraordinary height of two feet, and it issues from the burner with a noise that resembles that caused by the rush of steam out of a pipe; its colour is yellowish-white, and its temperature is that of the fusing-point of steel. The quantity of turpentine consumed by the lamp in connexion with the pulveriser is from two to five pounds per hour. Captain Schpakovski commenced his public experiments with the fusion of fine steel wire, which, after a few seconds, began to melt and burn away in sparks. He then gave the flame a horizontal direction, and melted a piece of copper. He also exhibited a crucible, intended, with the aid of the pulveriser, to melt pieces of copper weighing from five to ten pounds. The application to which Captain Schpakovski attaches the greatest importance, however, is the heating of the boilers of steamboats. He has constructed a small vessel, 24 feet long and 5 feet wide, with an engine of two horse-power, which performs 6½ knots an hour. The boiler is heated by four pulverisers, the turpentine being stored forward, and conducted through a tube, furnished with a regulator, to the pulverisers. The consumption of the liquid is stated to be equal to three pounds per hour per horse-power. The Captain is now engaged in the construction of a vessel of three times the above power, and he expects, in consequence of improvements in the boiler, to be able to reduce the consumption to about half the above amount. It is said that orders for twenty steamers for St. Petersburg and the neighbouring places have already been received, and that it is proposed to establish communication, by means of small vessels on Captain Schpakovski's principle, on the Neva, between the town and the islands, so that passengers may be conveyed through the canals of the Moika and of Tontaka to the central station on the Neva, where the large vessels lie that run between that place and the islands. It is not pretended that the heating by means of turpentine will cost less per hour than coals, but, as the former will not require the fires to be lighted more than ten minutes before starting, there will be a great economy in the case of very short runs like those on the Neva, which only occupy about half an hour. The new method is also applied to night signals, the lantern giving three times as much light as those at present in use.—*American Artisan.*

New Nantymwyn Mining Extension Company (Limited).—The object of the above Company is to acquire three lead-mining properties in Carmarthenshire—the new Nantymwyn, the Gilfach, and the Glan-Towy. A detailed account of each of these will be found in the prospectus.

Meetings for the Week.

Tuesday, March 12.

Royal Institution, 3 p.m. Professor Henslow "*On Botany.*"

Royal Society, 8½ p.m.

Friday, March 15.

Royal Institution, 8 p.m. Mr. E. B. Tylor "*On the Early Mental Condition of Man.*"

Saturday, March 16.

Royal Institution, 3 p.m. Professor Frankland "*On Coal Gas.*"

ANSWERS TO CORRESPONDENTS.

T. Aspden.—We have written to Paris for the gentleman's address.

Mica.—A correspondent says that he has extensive mines of mica in Canada, and could supply it in large quantities at a very cheap rate. He has about half a ton of it in England, and would be glad if some one could suggest a use for it.

W. Morgan.—Write to Hopkin and Williams, 5, New Cavendish Street. They will be able to supply the article you want.

Chemicus, Liverpool.—No examination is necessary to become a Fellow of the Chemical Society. You would have to be proposed by a member, and then ballotted for.

A. B.—The exact process of bleaching paraffin wax is a trade secret, and varies at every manufactory. One of the best processes is to melt and mix it with two per cent. of oil of vitriol, by means of which all the other hydrocarbons are carbonised. The remaining paraffin is then washed with hot water mixed with colourless photogen, and filtered hot through animal charcoal. The paraffin is thus rendered white, and may be separated from the photogen by distillation.

MacAdam.—We are unable at present to give our correspondent more particulars than are contained in the article alluded to.

E. C. C. Stanford.—The journal quoted can be seen either at the British Museum or at the Patent Office Library; or it can be procured from the Continent through Asher or Trübner.

H. B.—Tetrachloride of carbon has only recently attracted attention in the commercial world: we are therefore unable to give information on the manufacture, applications, and market of the same.

A. B.—The *Moniteur Scientifique* is published by Dr. Quesneville, Rue de Buci, 12.

Received.—"Fitzetlenne;" W. B; T. P. Blunt.

Books Received.—Dictionary of Chemistry, part xxxvii.: Sodium—Stilbite; Chemical Manufactories' Directory of England; the *Technologist* for March; Photographs of Eminent Medical Men, part i.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On Oxygenated Water, by M.* Schönbein.

The object of the present paper is to ascertain within what limits oxygenated water can resist spontaneous decomposition, or that provoked by heat. The author some time ago stated that oxygenated water, conveniently diluted, might, with impunity, be submitted to distillation; and he has now proved by experiments the correctness of this assertion. The test employed consisted of a standard solution of permanganate of potash, which is (as Mr. Brodie has shown) integrally reduced to protoxide of manganese, when in presence of oxygenated water.

As 100 grammes of the standard liquid contain four decigrammes of permanganate, there is then a milligramme of $\ominus$ per gramme of liquid, which destroys just as much $\oplus$ in the oxygenated water, provided, however, that the latter has been acidulated with sulphuric acid.

M. Schönbein has thus ascertained that oxygenated water is really weakened by boiling, but that nevertheless, when properly diluted, it is not wholly destroyed; so much is this the case, that it may even be concentrated by this means, and that generally, the more it is diluted with water, the better it resists the action of heat.

As to that which represents the deficit, it is not, as might be supposed, destroyed; it goes forth with the vapour, and condenses with it, so that oxygenated water is afterwards found in the receiver.

Metallic vessels should not be used in these operations, as they exercise a decided decomposing action on oxygenated water; while glass or porcelain is quite harmless. Cellulose also has no appreciable effect on it, for after soaking in oxygenated water either unsized paper or pure linen, and then drying,† the author has found in them the characteristics of oxygenated water by means of the following reagents—with tribasic acetate of lead, a yellow-brown precipitate; with a mixture of prussiate and ferric salt, a blue coloration. A similar coloration is also developed—1, by iodised starch, with the addition of a little ferrous sulphate; 2, in chromic acid, containing a little dilute sulphuric acid; 3, in tincture of guaiacum with the addition of some blood-corpuscles.

Dyed with indigo, and then plunged into a solution of diluted ferrous sulphate, the paper reagent quickly loses its colour, and the same thing happens when it has been dyed with cyanine blue.

Placed in dry and well-stoppered flasks, the paper will retain the power of producing these reactions for several weeks. It keeps especially well in dry air, but naturally loses its antozone when placed in ozonised air.

M. Schönbein has taken advantage of this property of lignin of fixing without altering HO_2, for ascertaining the presence of this peroxide in the vapour emanating from a liquid containing only $\frac{1}{2000}$ of HO_2. A strip of paper, dried over sulphuric acid, was, for this purpose, suspended in a flask containing the oxygenated liquid. In less than an hour the paper had acquired the property of turning blue in presence of iodised starch, much diluted, and with the addition of a trace of ferrous sulphate. The more concentrated the liquid, and the higher the temperature, the more quickly and the better does the paper become charged with oxygenated vapour, though it will become fixed even at 0°—a longer time being required for this. At about the boiling point, one minute is sufficient to blue even the ordinary ozone test-paper.

An almost equal sensitiveness is manifested by paper steeped in tincture of guaiacum, freshly prepared, then in corpuscles of blood; the same also with cyanine and indigo previously impregnated with ferrous sulphate.

After referring to his former researches on the production of oxygenated water, and proving that this body may be formed at a high temperature, M. Schönbein adds that we are far from being acquainted with the truth about oxidation, and that, for the present at least, we can hazard no theory of this phenomenon.

* *Journ. prakt. Chem.*, xcviii. 66.

† The water used contained ½ per cent. of oxygenated water.

TECHNICAL CHEMISTRY.

The Theory and Working of Blast Furnaces, by Wm. Crossley, *F.C.S., Manager Ormesby Iron Works.**

(*Continued from page* 114.)

Looking at these facts, it seems to the writer that what is wanted in the production of iron in the present form of blast furnace is the formation of carbonic oxide (CO) at the earliest possible moment after the blast enters the furnace, and also the greatest intensity of heat near the point at which it enters—in other words, localisation of heat with early production of carbonic oxide (CO). The recent improvements that have been made with a view of favouring the conditions for obtaining this object are two—

1st. Heating the blast;

2nd. Increasing the capacity of the furnace—

and I shall endeavour now to describe in what manner these may affect the combustion of coke and effect a saving in it.

On the first point I shall only risk one conjecture of my own.

Increasing the temperature of the blast gives increased affinity between the oxygen and the carbon, so that immediately the blast enters the furnace and comes into contact with the coke, combination takes place between the carbon of the coke and the oxygen of the blast; consequently the heat is more confined as to space, and more intense than if the combustion took place higher up the furnace, as it does where unheated blast is used.

I think there cannot be the slightest doubt about the importance of intensity of heat. In my opinion, without intensity of heat it would be impossible to make foundry iron at all, because, excepting at very high temperatures, combined carbide of iron cannot be decomposed into "graphitic" carbon and iron.† With some iron ores—as the Cleveland—it is almost an impossibility to make grey iron with cold blast, because with cold blast a sufficiently high intensity of heat is not obtained.‡

Again, the early removal of oxygen leaves a higher column of coke unacted upon, so that it is free to carbonise the iron as it trickles through; and it follows, also, that the sooner carbonic acid is formed—that is, the nearer the tuyeres it is formed—and nearer the tuyeres also is formed the carbonic oxide, and, lastly, the higher the column of material for the heated gases to pass through, therefore the cooler the gases are when they leave the furnace, and, further, more highly prepared is the material when it comes to that point where cast-iron and slag are formed. Thus, all the conditions

* Communicated by the author.

† I look upon "grey" cast-iron as a carbide of iron, but for my present purpose it will answer equally well, in discussing this question, to accept the view usually taken. See Chemical News, July 25, 1863.

‡ See *Transactions* of Society of Mechanical Engineers, Glasgow.

are better fulfilled with hot blast than with cold, and it is by contributing to the required condition in so high a degree—especially in the intensity of heat produced—that the hot blast effects such a saving in coke. At the same time, it must be admitted that the above does not altogether explain the results obtained, and perhaps the best further explanation of any that I have seen, or, indeed, that has been advanced, is the one given by Mr. Charles Cochrane. In this short paper I shall scarcely have time to give his views fully, but I trust to be enabled to make them sufficiently well understood.

In the furnace we have found that the coke is not perfectly burnt into the highest oxide of carbon, but only imperfectly burnt into the gas known as carbonic oxide, whereby it only gives out a very small portion of the heat it is capable of evolving; for instance, 1 lb. of coke, if properly burnt into carbonic acid, is capable of raising the temperature of 14,544 lbs. of water 1°, but if burnt into carbonic oxide only, the heat given out will be but 4453°, or in the proportion of 1 in the latter case to 3·26 in the former. Now it is very evident that any fuel that may be used outside the furnace and perfectly consumed, will be capable of saving the imperfectly burnt fuel inside the furnace in this proportion. Mr. Cochrane supposes that it is by heating the nitrogen of the blast from its initial temperature (say 50°) to a much higher temperature (say 1000°) by the perfect combustion of coal or other fuel outside the furnace, that so great a saving is effected; for instance, it is supposed that we force every minute 4500 cubic feet of atmospheric air into the furnace, and as 1000 cubic feet of air weighs 76 lbs., the weight of blast entering the furnace every minute will be 342 lbs., of which 263 lbs. is nitrogen.

$$\frac{263 \times 950 \times \cdot 25}{4453} = 14 \text{ lbs. carbon,}$$

per minute; and as this quantity of blast is capable of combining with 59 lbs. of carbon per minute, the saving in coke due to heating the nitrogen to 950° is about 25 per cent.

In my own opinion, we ought to take the oxygen of the blast into consideration, as well as the nitrogen, and in that case the saving would be about 18½ lbs. in every 59 lbs. of coke.

The next question for discussion is the capacity of the furnace and the relation between height and width. There cannot be the slightest doubt about the good hitherto resulting from increased capacity. It is well known that in some furnaces in the Cleveland district a saving of at least eight cwt. of coke per ton of iron made has resulted from this alone; but whether that benefit is due to increased width or increased height is not so easily determined. It seems to the writer that capacity—if that be all that is required—can be more easily obtained from greater diameter than from height; and the material, in wide furnaces, will have as much chance of absorbing the heat from ascending gases as in high ones, the only difference being that we have less gas passing over the same horizontal area than in the others; but inasmuch as it travels slower, the material has more time to absorb the heat it contains. But, apart from the question of absorption of heat and preparation of material, there is the equally important question of irregularity in the working of the furnace; for no saving in fuel can well compensate for "scaffolding" and "slips," and although 50 feet may be high enough for furnaces 18 or 20 feet in diameter, it may, for the purpose of promoting regularity in the working, be requisite to increase the height for a greater width. We ought, however, to consider well before adding much to the present height of our furnaces, with the great cost attending it, and also the increased working cost of raising material to great height.

The highest furnaces known are Messrs. Bolckow and Vaughan's, at Eston, which are 96 feet high. The widest furnaces are some building by Mr. Morrison, at Ferry-hill, near Newcastle, which are said to be 29 feet wide. Perhaps even greater good may be gained by increased capacity in the furnace, but it is evident a limit must be reached when the saving is counterbalanced by increased working expenses; and there can be no doubt this will be soon attained, for the temperature of the escaping gases is already reduced to 380° F. in furnaces 75 feet high and 21 feet wide. In furnaces 55 feet high and 15 feet wide, the temperature was 800° F.; and the saving in tons of coke per week in a furnace making 250 tons of iron per week on 25 cwts. of coke per ton, from this cause alone, will be

$$\frac{2949 \times 420 \times \cdot 25}{4453} = 69 \cdot 5 \text{ tons.}$$

The above calculation is made on the assumption that 2949 tons of gas is evolved per week; data from which above has been obtained will be given further on.

(To be continued.)

FOREIGN SCIENCE.

(From our own Correspondent.)

Paris, March 12, 1867.

The Mulhouse Industrial Society has proposed for the chemical arts the following subjects for prizes:—An important improvement in the bleaching of wool and silk. An industrial preparation obtained in the crystallised state from dye woods. A remarkable improvement in colour engraving. A better system of dyeing and soaping vats. Manufacture of an ultramarine, which, thickened by albumen and fixed by steam in the ordinary way, is not subject to any alteration, and preserves its clear and brilliant colour. Process of dyeing or fabrication of linen printed by organic bases. To prepare one or the other of the following colours:—metallic red, dark-green, and violet; also plastic garnet colour, capable all of being printed with a roller when thickened with albumen. A substance suitable for thickening colours, stucco work, and plaster, and capable of being employed with an economy of at least 25 per cent., instead of all the substances in use up to the present time for different purposes. Means of fixing charcoal grey otherwise and more solidly than by albumen. How do the molecular substitutions affect coloured organic compounds? Application, to the manufacture of printed goods, of the action of light and electricity upon the substances which are coloured by these agents. A substance able to replace, for all purposes, dry egg-albumen, in the impression of colours on tissues, at the same time presenting a considerable economy on the albumen. (Decolorised albumen from blood is cheaper than the albumen from eggs, always soluble in water, and capable of coagulating by heat.) Can indigotine be regenerated from its sulphuric components? What are the degrees of humidity and of heat at which the acetated mordants are decomposed most advantageously and the most rapidly? The employment of resins for the bleaching of cotton goods. New use of the yolk of eggs. Indelible ink for marking linen, &c. New machine with rollers capable of printing at least eight colours at a time. Solvents of aniline colours cheaper than the alcohols, having the same advantages, and not coagulating the thickeners. A process of fixing aniline colours more com-

pletely than by albumen. Introduction into commerce of caustic baryta at the maximum price of 15f. the kilogramme. New mode of treating different lubricating oils for machinery. The effects of different sorts of cotton in the bleaching and dyeing of tissues. Theoretical and practical study on cochineal carmine. Process of manufacturing aniline red otherwise than by arsenic acid. A simple, easy, and practical process of preparing the soluble protosalts. Aniline black soluble in any medium serving for dyeing, and able to resist the action of light as well as the aniline black already known. Aniline black for printing by rollers. A blue that can serve for tinting wools and for resisting vaporisation. Scarlet red derived from an alkaloid susceptible of applications similar to those of aniline, that will be less perishable than those, and not dearer than cochineal. Brown, maroon, and cinnamon colours from an organic base. Means of repeating, by a natural or artificial organic base of any description, the processes of the preparation of aniline colours, red, violet, blue, green, and black tints. The manner of forming the copper rollers for printing cotton goods, &c., so as to preserve their original diameter, without affecting the quality of the metal in the case of the application of a new design.

The chemical manures of M. George Ville commence to attract the attention of agriculturists, especially of those who have to grow great quantities of industrial plants, such as sugar-cane, beetroot, flax, &c. The following is the summary of the results of the experiments made by M. A. Cavalier at Mesnel-Saint-Nicaise (Somme) :—In a ground exhausted by four successive crops, obtained without manuring the land, giving only 18 hectolitres of wheat per hectare, instead of 28, the average return, six plots of ground were taken, of the size of an *are* each, and separated one from the other by a deep furrow. The following manures were applied :—To the first, five kilogrammes of sulphate of ammonia, two kilogrs. of phosphate of lime, two kilogrs. of common potash, two kilogrs. of lime ; to the second were added all the above elements except the lime ; to the third, five kilogrs. of sulphate of ammonia, two kilogrs. of pure phosphate of lime, two kilogrs. of lime, but no potash ; to the fourth, no nitrogen, two kilogrs. of pure lime, two kilogrs. of potash ; to the fifth, five kilogrs. of sulphate of ammonia, two kilogrs. of pure carbonate of potash, two kilogrs. of lime, no phosphate of lime ; to the sixth, no manure. No serious accident took place to hinder the vegetation from thriving, and the following is the result for the return of the crops per hectare (2·471 acres) :—For the first, complete manure 51 tons per hectare ; second, omitting the lime, 47·445 tons ; third, same complete manure, omitting the potash, 25·34 tons per hectare ; fourth, complete manure, leaving out the nitrogen, 36·834 tons ; fifth, same complete manure, omitting the phosphate of lime, 37·881 tons ; sixth, without manure, 25·550 tons. In comparing the first plot with the sixth, we perceive that the chemical manures have given an increase of the roots to an extent of 25·500 tons per hectare—that is to say, the produce is simply doubled ; beetroot being sold at 20 francs the ton and the chemical manure at 395 francs per hectare, the profit is equal to 115 francs.

M. Cavalier continued his experiments upon the plots of an are, each by transferring them to two hectares of ground —about 5 acres—and they were not less conclusive. The first hectare had received 650 kilogrammes of sulphate of ammonia, 800 kilogrs. of phosphate of lime, 200 kilogrs. of pure carbonate of potash, 200 kilogrs. of lime ; it produced 59·640 tons of beetroot, even when perfectly cleaned, and the leaves and fibres cut off. The second hectare had received the same manure, but with only 400 kilogrs. of sulphate of ammonia instead of 650 ; the produce was 45·325 tons of beetroot. These two series of experiments, well carried out, prove also that if the potash, the phosphate of lime, and the lime contribute very much towards the vegetation of the beetroot, the nitrogen seems to act the principal part.

M. Leroy, at Varesne (Oise), has made on his part experiments, the results of which are expressed by the following figures :—

Complete manure . . .	62·370	tons per hectare.
Same without phosphate .	48·330	,, ,,
Same without potash .	42·390	,, ,,
Same without nitrogen .	28·350	,, ,,
Phosphate of lime alone .	18·900	,, ,,
Lime alone . . .	9·450	,, ,,

If we consider the produce obtained on limed land as the expression of the real fertility of the soil, the complete manure gives a net profit of 52·920 tons.

In a quite recent note inserted on March 3 in the International Bulletin of the Imperial Observatory, and on the 8th inst. in the bulletin of the Scientific Association of France, M. Le Verrier resumes on the cometary theory of shooting stars, and persists in attributing the honour of it to himself without condescending so mention the name of Schiaparelli, whose letters, however, have been published in a journal of great authority, the meteorological bulletin of the College of Rome, issued under the superintendence of the Rev. P. Secchi, and were translated by the writer before M. Le Verrier had published a single word of his researches. We are really frightened by this system of organised cool-blooded appropriation, and more so by these lines, the effect of which has been even more coolly calculated :—*Sir John Herschel, who, along with his son, Alexander Herschel, has paid great attention to shooting stars, gives his complete assent to* the theory of the swarms of November. Poor M. Schiaparelli ! Happily the *Astronomische Nachrichten* have collected the necessary papers, and he will soon be in a position of having his revenge.

M. Mohn, director of the Meteorological Institute of Norway, has proved by numerous observations the extraordinary influence of the ground on the direction of the wind which blows against the coasts in winter. During the month of January, the cold air which covers the earth flows towards the sea, comparatively warm, producing thus a really constant land breeze, which modifies and diminishes the velocity of the gales in the upper portion, and alone can pass the mountains ; rejected by the cold air of the earth, the lower portion takes a southern direction without being able to reach the land.

On November 14 last, the sky being clear, M. Mechin, who was travelling towards Ispahan (Persia), observed, in all its splendour, the shower of shooting stars. Every second millions of luminous points dropped from the firmament and fell into space. Several stars trained a long tail like that of a rocket. F. Moigno.

Paris Exhibition, Chemical Department.—We understand from Mr. Howard, Chairman of Class 44, that Mr. Bockbinder (Messrs. Mazaroz's representative in London), who has gone over to Paris to look after the interests of exhibitors who had placed their cases in his principals' hands, that the cases are all erected, and the allotments consequently secured. The glazing will commence immediately, and he has no doubt but that every case will be ready for the reception of goods by the 20th, before which time it will be useless for exhibitors to think of unpacking their goods, owing to the dirt and confusion. A number of men are employed by him in collecting the packages of goods of each exhibitor, and placing them before the cases. Owing to the overworked condition of the railways, it will be of little avail making inquiries about individual missing packages just at present, but we learn that the consignments are coming forward with fair regularity, and there is no doubt but that the regulation as to March 10 will be relaxed.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, March 7.

DR. W. A. MILLER, M.D., F.R.S., *President, in the Chair.*

THE minutes of the previous meeting were read and confirmed. Messrs. George Ottley and Joseph Ince were formally admitted Fellows of the Society, and the following gentlemen were duly elected—viz., Major R. C. Stewart, Deputy-Assistant Adjutant-General to the Forces, Horse Guards; Mr. James Campbell Brown, Aberdeen; Mr. William Price Bonner, 69, Mark-lane; and Mr. J. Hersee Freeman, Stratford-house. The names of candidates proposed were Mr. John Mackay, 119, George-street, Edinburgh, and Mr. David Skinner Kemp, Bombay.

Mr. E. T. CHAPMAN read a short paper "*On the Oxidation of Formic Acid.*" The author finds that formic acid will not survive the oxidising influence of an aqueous solution of chromic acid, being in this respect entirely different from the acids both of the acetic and aromatic series, which have been lately shown to resist a treatment of this kind. A quantitative result was quoted in support of the fact of formic acid being converted under these circumstances into water and carbonic acid.

A "*Note on the Synthesis of Formic and Hyposulphurous Acids,*" by Dr. A. Dupré, was next read. After Kolbe had demonstrated the synthesis of formic acid by the action of an alkali metal upon carbonic acid, the author conceived that a parallel reaction would give rise to the production of a hyposulphite. The change duly occurred when sodium amalgam was brought into contact with aqueous sulphurous acid, thus—

$$2SH_2O_3 + 2Na = SHNaO_2 + SHNaO_3 + H_2O.$$

No formic acid was generated by the action of zinc upon an aqueous solution of carbonic acid heated in a sealed tube, but distinct traces of the acid were obtained by boiling under pressure gas-coke, or carbon obtained from tartar, and a strong solution of an alkaline carbonate, and afterwards distilling with sulphuric acid. The author considers it probable from his experiments that the constitution of formic and hyposulphurous acids is identical, and that the atomic expression of the latter may be simplified by adopting a halved formula, thus—

$$Na_2H_2S_2O_4 = 2(NaHSO_2).$$

Hyposulphurous acid would thus become the formic acid of the sulphur series.

Mr. CHAPMAN confirmed the observation of Dr. Dupré, by stating that a formiate was generated by the fusion of carbon with a caustic alkali and pouring the hot mass into water. Another method of synthesis was noticed in the case of dissolving cast-iron nails in chromic acid and distilling the product.

Dr. F. CRACE CALVERT gave some details which he had observed in the manufacture of formic acid by the oxalic acid and glycerine plan. The product seemed to be formed tardily at first, but on repetition of the process with the same glycerine and fresh amounts of monohydrated oxalic acid the action unfolded in a very regular manner.

Dr. ODLING offered some remarks in support of the opinions advocated by Dr. Dupré, whose experiments were first commenced in his laboratory. The destruction of formic acid under circumstances where acetic acid survived was capable of explanation on the ground that there might be, as assumed by Laurent, differences between the mono- and bi-carbon acids as great as between those containing three and four atoms of carbon. Dr. Calvert's anomalous result might be the consequence of the production in the first instance of a formiate of glycerine which subsequently became decomposed.

Mr. CHAPMAN preferred to assume that an oxalate of glycerine was first formed which split up under the action of heat into formic and carbonic acid with regeneration of the glycerine. The speaker did not object to halving the formulæ of the hyposulphites, but would not allow that sulphur plays the part of carbon, or that there was any analogy between the two acids under discussion.

Dr. F. CRACE CALVERT made a preliminary statement of the results of a series of experiments in which he is at present engaged. The author finds that a large proportion of the mineral phosphates contained in cereal grains, peas, beans, and even cotton, may be extracted by digestion in water. The solutions thus obtained always held in solution much magnesia. Cotton wool of twelve kinds was operated upon, and the amount of phosphoric acid extracted was about one two-thousandth part of the original weight of the vegetable substance. He had determined in several instances the proportion of phosphates before and after treatment with water. Dr. Calvert also mentioned incidentally a fraudulent practice of adding weight to cotton goods by brushing over them an aqueous solution of chloride of magnesium.

Mr. SPILLER said that the observation of Dr. Calvert reminded him of an experiment which Dr. A. W. Hofmann used to show in his course of lectures at the Royal College of Chemistry—namely, that by the addition of ammonia to the aqueous extract of malt, or pale ale, an abundant precipitate of white crystalline ammonio-magnesian phosphate was formed.

The PRESIDENT confirmed this statement by remarking that Liebig had shown him the same experiment many years ago, whilst on a visit in Germany.

Dr. CALVERT described likewise some interesting results obtained by the action of carbon (boxwood charcoal) impregnated with oxygen upon a variety of compounds; thus sulphurous acid and sulphuretted hydrogen were both immediately converted into sulphuric acid, alcohol became acetic acid, wood spirit was changed into formic acid, fousel oil into valerianic acid, &c.

The PRESIDENT moved a vote of thanks to the respective authors, announced the date fixed for the members' dinner (27th instant), and adjourned the meeting until March 21.

PHARMACEUTICAL SOCIETY.

March 6, 1867.

G. W. SANDFORD, *Esq., President, in the Chair.*

Dr. JOHN HARLEY, F.L.S., read a paper "*On Some of the Preparations of Conium of the British Pharmacopœia.*" The author has, during the last few months, been engaged in ascertaining the value of the conium preparations; he published the result of his experiments with the tinctura conii fructus of the British Pharmacopœia in the January number of the *Pharmaceutical Journal.* These experiments went far to prove that the tincture is almost useless as a remedial agent, for Dr. Harley has not only administered it to patients in large doses without perceiving any of the effects of conium, but he has also taken it himself, in doses varying from ʒss. to ʒij., without experiencing any effect, excepting a stimulant action from the larger quantities of spirit. There was no sense of fatigue, neither drowsiness nor tendency to inaction, no disorder or diminution of muscular power. The pupil, definition in the vision of near and distant objects, the pulse, and all the functions remained in their usual state, and the secretions were active and normal, so that it is evident that the tincture is an inert preparation when given in proper medicinal doses. Dr. Harley now gives the result of his experiments with the succus conii, which he described as a useful preparation. He had taken it in doses varying from ʒij. to ʒvss. The first dose was taken without any effect, but after the larger doses he experienced to a greater or less degree those symptoms which had not followed the large doses of the tincture. He believed that

the use of tobacco greatly interfered with the effects of conium. A person who smoked half an ounce of tobacco in the day would become less excited after a dose of a preparation of conium. The author said that he was now engaged in ascertaining the value of the extract; up to the present time the results he had obtained were unsatisfactory, but he hoped to publish further researches on the subject. He then drew the attention of the meeting to some preparations of conium which had been carefully prepared by Mr. Hemingway from the fresh plant, and also to a preparation which had retained its properties unimpaired for three years.

Professor Redwood could not recollect the exact wording of a communication received from Dr. Christison, but he believed it was to the effect that Dr. Christison had a sample of extract of hemlock prepared twenty years ago by the late Mr. Jacob Bell, which still retained its efficacy as a medicine.

Mr. D. Hanbury thanked Dr. Harley for his paper, and referred to Dr. Harley's zeal in conducting these experiments on himself.

Dr. Harley said that it was usual to perform experiments on the lower animals, but he believed this was in many cases insufficient.

Dr. Attfield also thanked Dr. Harley for his paper, saying it was a subject of especial interest to them as pharmaceutists.

Mr. D. Hanbury, F.L.S., read a paper "*On the Necessity of the Cultivation of Medicinal Plants.*" He had intended to read a paper "*On the Cultivation of Jalap,*" but he afterwards thought it desirable to alter the title. After remarking that those medicinal plants which were indigenous to our own country were cultivated with care and attention and collected at a proper time, Mr. Hanbury referred to the various causes of the high prices of many important drugs, mentioning scammony, jalap, kino, ipecacuanha, &c., saying that he believed they would be procured at lower prices, and in better condition, when cultivated by civilised and intelligent men. He also mentioned calumba, hemidesmus, chiretta, &c., as plants which would be materially improved if they were cultivated by the aid of intelligent skill. Mr. Hanbury concluded his paper by commending the subject to their further attention.

The thanks of the meeting were given to Mr. Hanbury for his interesting paper.

Mr. A. F. Haselden commenced reading a paper "*On the Codex and the British Pharmacopœia compared;*" but as the time had expired before Mr. Haselden had proceeded far with his paper, he consented, at the request of Professor Bentley and the Chairman, to postpone it to the next Pharmaceutical meeting.

ROYAL INSTITUTION.

A Course of Six Lectures "*On Coal Gas,*" by Dr. Frankland, F.R.S. (Lectures I. and II.—March 7 and 9, 1867.)

Sketch of the Apparatus and Processes used in the Manufacture, Purification, and Distribution of Coal-gas—The Philosophy of the Light of Coal-gas—Source of Light in a Gas Flame—Comparison of the Illuminating Effect of Gas with that of Candles—Construction and Use of Photometers.

In the first lecture the ordinary process of gas manufacture was briefly explained, by means of diagrams and by an experiment, in which the process of manufacture was followed as far as could be expected in a lecture. The several gases of which coal-gas is chiefly composed were individually examined with regard to the amount of light yielded by them. Dr. Frankland then proceeded to an inquiry, which, from the novel way in which he treated it, possessed great interest—"What is the source of light in a flame? Does it proceed from the suspension of incandescent particles?" This, it is well known, is the usual explanation of our text-books, but the lecturer had recently been led to doubt its truth. The audience were invited to follow an experimental examination of the facts in support of and those in opposition to the generally accepted theory.

Non-luminous flames—such as hydrogen and carbonic oxide—were burnt from jets, and very finely divided carbon sifted into the flame; the luminosity then approached somewhat to an ordinary gas flame. A plate was held over a non-luminous flame, and there was no deposit; a luminous one treated in the same manner deposited sooty matter. These experiments appear to support the received explanation of the phenomenon.

Hydrogen and oxygen, when enclosed in a strong vessel and ignited by an electric spark, gave a brilliant flash; evidently no solid particles can exist in this flame. Hydrogen was burnt in atmospheric air, and subsequently in chlorine gas. Though not very great, there was a marked increase in the luminosity; this, again, cannot result from solid incandescent particles.

Bisulphide of carbon, ignited in atmospheric air, gave little luminosity, and upon a cold surface deposited a little sulphur; fed with a stream of oxygen, the brilliancy of the combustion was greatly increased; no sulphur or carbon can exist unoxidised in this flame. Other experiments in opposition to the old theory were the combustion of a mixture of nitric oxide and the vapour of bisulphide of carbon, and of arsenic in oxygen. These experiments at least prove that a brilliant flame may be produced under circumstances in which no solid incandescent particles can exist in the flame.

A few experiments were shown to indicate that temperature exerted an effect upon the light-giving power of flames.

The increase of light produced by the combustion of sulphur in oxygen, in comparison with sulphur burning under ordinary circumstances, was attributed to the great increase of temperature. The vivid combustion of phosphorus in oxygen was explained in the same manner. The lecturer did not believe that the great luminosity in this case was dependent on the suspension of solid particles, for the reason that the product formed would be volatilised at the enormously high temperature produced; but he did not advance this example as pointing with the same conclusiveness as the preceding experiment. Temperature apparently exercises an effect upon the flame.

The bearings of experiments performed previously, but the description of which we have preferred to defer till now, were examined with regard to the density of vapours and gases. These experiments were the combustion of a mixture of oxygen and hydrogen, and of hydrogen and chlorine, under circumstances which admitted of free expansion. These mixtures, in fact, were exploded, and the attention of the audience was drawn to the almost absence of light. When these experiments are contrasted with those made under which, in the one case, the great expansion was resisted, and in the other case—that of hydrogen and chlorine—in which it did not come into play (the combination taking place in insufficient quantity to produce a sudden rise of temperature), they cannot but strike an observer with the fact that vapour density exercises some influence on the luminosity of flames. This was still more apparent in the following experiment:—Arsenic was burnt in oxygen, in an apparatus which enabled a partial vacuum to be created, and the supply of oxygen to be regulated. Upon diminishing the current of oxygen, and partially exhausting by means of an air-pump, the light became gradually fainter and fainter.

A diagram exhibiting the vapour densities showed that steam, hydrochloric acid, carbonic acid, and arsenious acid possessed greater vapour densities than hydrogen, the numbers ascending in the order in which they occur immediately above. Experiments in which these compounds

were produced by combustion followed the same order, the combustion of hydrogen and chlorine giving, next to hydrogen, the least light, while arsenic in the oxygen gas gave the most.

Dr. Frankland stated that he believed the luminosity of a gas flame was due to the condensation of hydrocarbons richer in the number of atoms contained in a standard volume than the original constituents. The suggestion was thrown out whether the sooty matter deposited on a coal surface might not in great part consist of rich hydrocarbons such as pyren and cyren. Certainly hydrogen, as was mentioned, is known to exist in it.

The conclusion of the second lecture was devoted to the methods of estimating the amount of luminosity possessed by flames. The shadow photometer and Bunsen's were described, and their use shown. Dr. Letheby's modification of Bunsen's photometer was likewise exhibited, which, though it depends in the first principle upon Professor Bunsen's, is so greatly elaborated and improved as to possess a far higher degree of accuracy.

MANCHESTER LITERARY AND PHILOSOPHICAL SOCIETY.

PHOTOGRAPHICAL SECTION.

February 20, 1867.

Dr. J. P. Joule, *F.R.S., &c., Vice-President of the Section, in the Chair.*

A paper, by Joseph Sidebotham, Esq., was read, "*On the Reversed Action of Light in Photography.*"

Those who have for many years been engaged in photographic pursuits, either as amateurs or professionals, have (especially when trying some new process) met occasionally with very curious results—failures as photographic pictures—but of the greatest value as remarkable results of the effects of light. These were probably much more frequent in the early days of photography, when we were dependent in a great measure on our own manufacture of chemicals, even to the preparation of ether. Unfortunately but few of these curiosities, as we may call them, have been preserved; in the desire to produce good pictures these have been thrown aside, and too often the causes of the strange results have not been ascertained. This is the more to be regretted as discoveries of great value may be hidden under these so-called failures. On a former occasion I exhibited here a collodion positive, on glass, of a landscape, with the natural colours, red, green, and blue, very fairly represented, although much duller than in nature. This was an over-exposed picture, and not noticed particularly until a day or two after it was taken, and all my subsequent attempts were unsuccessful to obtain another similar picture.

It is well known that when plates are over-exposed in the camera the action of light becomes reversed; thus, a sky which ought to be black becomes transparent, and a print from this looks somewhat like a negative on paper. Still the action is by no means regular, and there are many points connected with this action which require careful investigation.

It is my intention to bring some of these before you this evening in a brief manner, and to exhibit some curious specimens in illustration.

All photographers must have noticed now and then, where two lines of light and dark meet, that the light is rendered more intense just at the edge of the black or dark object. In portraits of gentlemen this is sometimes very prominent; the dark figure is thrown up as intended from the light background, but the latter is so much more intense just round the figure that it has sometimes the appearance of light streaming from behind. This effect is sometimes seen in landscapes—round a tower or even a tree projected against the sky runs a line of intense white much deeper than the sky itself. On the other hand, it sometimes happens that in a landscape with mountains the edge against the sky seems to be robbed as it were of a portion of its intensity, and so when printed exhibits a dark edge.

Again, it is well known that the sky, seen through small openings in trees or small windows in a ruin, is much more intense in a negative than the great mass of the sky; also that in taking an interior view, where light streams through a window in front of the camera, the effect produced on the negative is as if the light came round, illuminating to some extent the inside, and gradually as it were eating away the tracery of the window.

In some cases where the bright sky is seen through an opening of the trees, the trees and branches around the opening are converted in the photograph into pure white tracery on a darkened sky, and the remainder of the picture quite natural; in some cases, again, one half of a photograph may be correct as a positive, and the other, the distance exactly like a paper negative. I bring with me for exhibition specimens of these several effects, which appear intimately connected together, and deserving of our attention.

The question for us to consider is whether these effects are to be accounted for altogether by the received theories of the reversed action of light on iodised plates or paper when exposed too long in the camera—in other words, what used to be called solarisation—or whether, to some extent at least, these are not copies of the natural effects as the camera sees them, and as we should see them if we looked aright.

In Tyndall's work on the glaciers of the Alps is a reference to a curious phenomenon he saw, where the trees and shrubs projected against the sky showed as brilliant white. He says this phenomenon is rarely seen by guides or travellers, perhaps because they avoid looking towards the brilliant sky. He also quotes a letter from Professor Necher to Sir David Brewster, describing the same phenomenon. He says he has seen it at different times of the day, and says that the appearance of the trees projected against the sky is as if they were made most delicately of the purest silver. At pages 180 and 181 are sketches, which, as you will see, are wonderfully like the photographs I have to show.

That some of these effects can be accounted for I am well aware, but when taken together there is much that is inexplicable; the explanation for one case will not suit another. I would, therefore, make the suggestion that, in some states of the atmosphere, these bright lines are to be found in nature, either visible, or of such actinic power as to produce the results you see; there are certain effects in nature—for instance, the streaming light of the sun from behind clouds—of which the camera takes no notice, and on the other hand, there may be effects in nature invisible to us, but which act like invisible rays of the spectrum with great chemical intensity.

The following photographs were exhibited to illustrate the above remarks:—

No. 1. Showing white lines round figures, and chair in carte de visite portrait.

No. 2. Showing white line round church tower and yew tree.

No. 3. Showing white line faintly above the hill, also the increased depth of shade at the extreme top of it.

No. 4. Showing intense white line dividing landscape from sky, also the railings on bridge against the sky showing intense white, whilst those against the trees are black.

No. 5. Curious compound of positive and negative, the house, road, trees, &c., in foreground being positive, and correct, the sky black, and the distant trees and buildings white.

No. 6. Bridge and stream, Fountains Abbey. Showing the foliage around the opening to sky traced in pure white, the other part of photograph being natural.

No. 7. Showing the blurring of dark tracery when light streams through a window.

No. 8. Showing one of the distant hills reversed, appearing light against a dark sky, the other mountains appearing natural.

Mr. Dancer remarked that several years since he had attempted to explain the marginal appearances which some photographic negatives exhibit, by supposing that the force which governed the deposit forming the picture was more energetic at the abrupt boundary line between a light and dark object than on other parts of the exposed sensitive plate where there was less contrast, this intensity of force bearing some analogy to that which is observed on the edges of bodies influenced by magnetic, electric, or chemical action. More recent observations had induced him to alter this opinion. He thought the phenomena were caused by interference of light accompanied by diffraction fringes of colour produced by the projection of a dark body against a bright sky. The actinic effect of these fringes might possibly be increased or decreased according to the amount of chromatic correction of the camera lens for the primary and secondary spectra. Mr. Dancer stated that he had frequently noticed the reversed action of light from over-exposure; with the old daguerreotype process he had obtained very perfect negative instead of positive pictures. On one occasion, in 1840, he accidentally exposed an iodised daguerreotype plate in the camera much longer than the usual time; in this picture the natural colours of the objects were brought out in a marked degree. This picture he exhibited to many friends, but from not being fixed it faded after some time. Subsequent attempts on the same objects failed in obtaining the natural colours.

SOCIETY OF ARTS.

On the Synthesis and Production of Organic Substances and the Application which some of them receive in Manufactures, by Dr. F. Crace Calvert, *F.R.S., F.C.S., &c.*

Lecture II.

(*Continued from page* 105.)

It may be interesting to some of my hearers to know what changes take place when fruits are converted into jelly or marmalades; and whilst on this subject I may state that there is no doubt that a part of what is sold as Scotch marmalade is made from carrot juice, sweetened with a little sugar, and rendered bitter with peel of the bitter Seville oranges. I have the pleasure to present to you some marmalade and jellies that have been made from carrots, and which, from their quality, leave no doubt that, with a little skill and practice, a very agreeable condiment can thus be produced. But setting this aside, let me state that when fruits are heated the pectase converts the pectose of the fruits into pectine, and if then sugar is added, and the whole filtered, the pectine solution, as it cools, becomes gelatinous, and constitutes the ordinary fruit jellies; but ladies or cooks must take great care not to boil these too long, or they will get into a chemical difficulty, for, under the influence of heat, pectine will first be converted into pectic acid, and then into metapectic acid, when no jelly will be produced. Therefore, great care must be taken not to boil the fruit syrup with the sugar more than a few minutes before it is clarified with a little albumen, or white of egg, filtered, and allowed to cool.

Having thus studied some of the interesting conversions of starch into sugar, under the influence of artificial and natural chemical actions, let us examine together the transformations which sugar is capable of undergoing under various chemical and molecular actions; and this cannot fail to interest you, as man has availed himself of these transformations to obtain some of the most abundant and valuable products which he employs, either for his health or as a beverage. It is especially the transformation of sugar into alcohol on the one hand, and the conversion of alcohol into various products; and, on the other hand, the transformation of sugar into mannite, the sugar of manna, or its conversion into lactic acid and butyric acid, that I wish to dwell upon for a few minutes. Several of the conversions of sugar into other substances are effected under the peculiar action of certain ferments, which ferments are microscopic plants or animals.

Having already explained the conversion of sugar into alcohol by means of a ferment, and the further transformation of that alcohol into acetic acid by another ferment—the one called *Mycoderma vini* and the other *Mycoderma aceti*—it would be loss of time to enter again into the subject here; but there is one fact which has come to light since then, and which appears to me sufficiently interesting to justify my calling your attention to it. I stated last year that many of the diseases to which wine is subject were not due, as was believed by chemists and others, to mere chemical transformations of the various substances constituting that liquid, but to peculiar and well-defined ferments which develope themselves in that fluid under special circumstances, and which are the cause and the source of various classes of disease to which wines are liable. The knowledge of these facts has proved most valuable, for it has enabled M. Pasteur to devise a very simple method for arresting the decomposition or decay of wines. M. Pasteur's plan consists in heating diseased wine to a temperature of about 130°, when the ferments are destroyed, and all that is necessary to restore the wine to its original state is to allow the dead ferments to settle as a deposit, and then to decant the wine.

I may state here, *en passant*, that a M. Lamotte has proposed and carried out with success a method of "ageing" wine rapidly. It consists in submitting the wine for a few days to a temperature of about 100°, when it will be found that, after allowing the wine to stand for a short time, it has acquired the flavour of a seasoned vintage.

Let me resume the subject of my lecture by stating that the transformation of sugar into mannite is also due to a peculiar ferment, which is a modification of the *Mycoderma vini*, for this ferment is produced by boiling in water the ordinary one, and then mixing the so boiled ferment with a saccharine fluid; a very slow fermentation ensues, the saccharine solution becomes viscous, and if then its composition is ascertained it is found to be represented by a gummy, neutral, viscous substance, and a crystallised white matter, called mannite, one of the chief constituents of manna, which is used as a purgative in pharmacy. If, instead of introducing into a sugar solution one of the above-mentioned ferments, it is mixed with albumen, or the curd of milk, or several other animal substances, and chalk added, after a short time the mass assumes a thick gelatinous appearance; and if then it is chemically analysed, it will be found that the sugar has unfolded itself into lactic acid, each equivalent of sugar giving rise to two equivalents of this acid, a substance which is found to characterise the acidity of milk, and which also exists in the gastric juice of man and many other animals, also as acid lactate of lime in the muscular flesh of man and of animals, and which, lastly, is also a constant product in the slow fermentation of flour, in warp-sizers' vats, and in curriers' clearing pits. We thus observe the value of a science which is able to trace, to define, and to characterise the production of a substance from its original source—namely, starch or sugar into the stomach of man—and to proceed from thence into the manufacturer's operations such as those which we have just mentioned. A science which can so well trace the production of a substance and its influence in the medium in which it is found to exist, and can give, as I have shown in my former lectures, an explanation of the various functions it fulfils in the instances I have cited, must be indeed a science worthy of your attention, and worthy of the encouragement of the members of this Society.

There is still another transformation of sugar, through the medium of a ferment, which is not less curious and instructive than those just referred to. Here the transformation is not due to a vegetable ferment, but has been traced and proved to have its source in animal life. The ferment is represented by a little microscopic straight figure having a vibratory motion, and hence called *vibrio*. These microscopic animals transform sugar into that noisome fluid which characterises rank butter, called butyric acid, and which substance in its turn can be transformed, as I shall tell you in my next lecture, into a compound called butyric ether, sold in large quantities as the fruit essence of pineapple, used extensively for imparting that flavour to sugar drops.

Since I delivered this lecture to the Society of Arts, there has appeared a paper by M. Bechamps, which presents such a peculiar interest that I must be excused if I here introduce it to the notice of the reader. This learned chemist has gone a step further than Ehrenberg, who stated that most of the chalk formations were represented by the remains of microscopic animals, several of which, by the perfection of their fossils, he was able to define and name. But Bechamps has discovered that, besides the remains of antediluvian periods, there exist at the present time large quantities of microscopic animalcula, which he has named *Microzyma cretæ*, found by him to exist in the centre of large blocks of chalk, taken out at a depth of 200 feet under the surface of the soil by means of a tunnel driven into the sides of a mountain. What enhances the interest of this discovery is that, if some of this chalk is placed in a saccharine solution, butyric and lactic fermentation ensue.

(To be continued.)

ACADEMY OF SCIENCES.

(From our own Correspondent.)

March 4, 1867.

The correspondence was absolutely *nil*.

M. J. E. Benjamin Valz, formerly director of the observatory of Marseilles, born at Nismes, May 28, 1787, died at Marseilles, February 22 last. He was a sincere lover of astronomy, and devoted his entire life to it. He published a great number of notes and scientific memoirs; and to have become for ever celebrated, all that was necessary for him was to have had a little generosity. Being a rich man, he should have spent a little money for the necessary repairs of the Marseilles observatory, and remained there at his post up to his death.

M. Becquerel (elder) read a paper on the study of the variations of temperature of the ground at different depths, made by the aid of the electric thermometer. The conclusions arrived at are the following:—

1. At 1 metre beneath the surface of the ground the mean temperature continues increasing from winter to summer as in the air. The difference between the maximum and the minimum is 6° C. in the ground, and 18·17° in the air.

2. At 6 metres deep the variations occur in the inverse order, the maximum taking place in winter; the difference between the maximum and the minimum is 1°.

3. At 11 metres deep the variation is not more than 0·3°; the maximum takes place in winter, the minimum between the spring and summer.

4. From 16 to 26 metres the variations follow the same law as in the air, with this difference, that the difference between the maximum and the minimum is only 0·27° C. This anomaly or inversion of the law is due to the infiltration of water through permeable strata. M. Delesse has found that 16 to 26 metres are the depths of the water beds which supply the wells of the Jardin des Plantes and the neighbourhood.

5. From 26 to 31 metres the variations follow the laws the opposite to those of the air.

6. From 31 metres the variations of temperature attained scarcely 0·12°, the temperature being sensibly constant.

M. Kirchhoff transmitted, through M. Henri Sainte-Claire Deville, an answer to the objections of M. Faye against his theory of the spots on the sun, which he attributes to two clouds superposed, and formed, the lower one directly by the cooling of the solar photosphere, the other superior by influence. M. Faye replied immediately, and maintains that the explanation of the illustrious German physician is not in any way astronomical, and is not supported by any observation. M. Faye read afterwards a last memoir for the purpose of answering the difficulties that the movement of certain solar spots opposed again to his theory of the solar reflection and parallax. He has confirmed the fact, which passed unnoticed up to the present time, that when, after the apparition of a beam or fillet of light thrown from one side to the other, a spot is divided into two parts, one of the halves, as if it had received an impulse in front, takes an abnormal motion of its own, while the other half continues alone its normal movement, with variations of velocity which only depend on the latitude.

M. Blanchard communicated, in the name of M. D'Arrest, Professor of the Faculty of Lille, observations tending to prove that slight embryogenical deformations or monstrosities can become the starting-point of the constitution of a race.

M. Le Roux read the *résumé* of his experimental researches on the velocity of propagation of a concussion communicated to a gaseous mass enclosed in a cylindric tube. His aim was to measure it at a uniform temperature. The conclusions arrived at from 77 determinations, taken by processes quite new, that the propagation of the concussion is 330·66 m. per second. It is an approximation within $\frac{1}{1600}$th part.

March 11.—*Public Annual Meeting.*

M. Laugier, the President, proclaimed the prizes awarded for the year 1866; M. Delaunay gave a lecture on the moon and its importance in astronomy; he replaced M. Elie de Beaumont, who was to have enumerated the services of one of the members deceased. With the exception of the great prizes of mathematics, for which no competitors presented themselves, and the subject being passed in silence, the choice of the laureates, however, is admirably made, and with excellent intentions. The lecture by M. Delaunay on the moon was very interesting; he analysed all the astronomical labours thereupon, from Newton down to our present day. Differing from the school of Laplace, he gave to the earth's satellite the providential functions with which she is endowed. One is to enlighten the earth, but there are others which are sacrificed to the first. The crowded assembly remained calm, but attentive; they applauded the speaker when at the end he pleaded nobly the cause of science purely speculative, which has often a result of great future utility, although for the present it seems completely sterile. The prizes were rapidly distributed.

Prize for Astronomy.—Mr. MacLear, for the mensuration, at the Cape of Good Hope, of an arc of the meridian, and the publication of his great work, "Verification and Extension of La Caille's Arc of Meridian at the Cape of Good Hope," two vols., 4to. The celestial amplitude of the arc measured by Mr. MacLear differs only by a small fraction of a second from the amplitude found by La Caille, and this agreement contributes to maintain the reputation of the French astronomer.

Prize for Mechanics.—M. Tresca, for his celebrated studies on the flowing of solids under heavy pressure.

Prize for Statistics.—Dr. Brochard, for his memoir on the mortality of nurslings in France.

Most honourable mention was given to M. Parchappe,

for the reports on the central prisons and houses of correction.

Honourable mention to Dr. le Fort for his work on foundling hospitals and the charitable institutions for the accouchement of women at their houses in the principal States of Europe; to Dr. Girard de Cailleux for his statistical documents on lunatic asylums at Auxerre.

Bordin Prize, 1866.—Determination of the indices of refraction (with respect to the spectral lines) of glasses of different sorts which are employed for optical or photographic purposes. M. Baille, of Aix (Bouches du Rhone), obtained the prize; honourable mention to M. E. Mascart.

Bordin Prize, 1864.—Determination of the lengths of some well-defined rays of light; the prize given to M. Mascart. His memoir in the report is certainly the deepest and most satisfactory that has been made since Fraünhofer relative to the lengths of wave of which the light is composed. And M. Angström!

Frémont Prize.—For having aided a *savant*, without resources, in the expenses of labours and experiments for discoveries or improvements in the sciences or the liberal arts. Presented to M. Marc-Antoine Gaudin, the disinterested author of molecular morphagen and so many inorganic experiments.

Prize for Experimental Physiology.—Honourable mention to M. Colin, Professor at the School of Alfort, for his experiments on anomalous heat; also to M. Philipeaux for his experiments on the regeneration of the spleen of animals. M. Knoch, of St. Petersburg, for his new researches on the broad bothriocephalis. M. J. Cheron, for his researches on the dibranchial cephaloda.

Prize for Medicine and Surgery of 100*l.* to Dr. Béraud for his surgical, topographical, or regional anatomy; 100*l.* to M. Anger for his iconographic treatise on surgical maladies; the same to M. Marey for his researches on the nature of the contraction of the muscles in animal life. Honourable mention, with 60*l.* recompense, to M. Labarde for his work on softening and congestion of the brain; to M. Sappay for his researches on the structure of the fibrous and fibro-cartilaginous parts; to Henry Lionville and Augustus Voisin, for studies on curare. Honourable mention to M. Demarquay for his essay on medical pneumatology; Dr. Labordetta for his speculum of the larynx; M. Bouchut for his work on diagnosis of the maladies of the nervous system by the ophthalmoscope; M. Empis, granulous diseases known by the name of brain fever, granulous meningitis, galloping consumption, &c.; M. E. Fournié, physiology of the voice; M. Cahen, cholera, and treatment by arsenic; Dr. Lemaire, phenic acid and its action; Dr. Gimbert, structure and texture of the arteries; Dr. Polaillon, structure of the nervous peripheric ganglions.

Prize for the Application of Electricity to Therapeutics.—(Postponed for three years.) A medal of the value of 60*l.* was awarded to Dr. Namias, of Venice, for the unceasing efforts he has made in order to respond scientifically to the question proposed by the Academy, and the interesting observations he has already made.

Grand prize for Surgery, for the preservation of the limbs by means of the periosteum. The prize of 800*l.* was divided equally between M. Sedillot, chief surgeon of the army and the Faculty of Strasburg, the inventor of the method of extracting the interior of the bones, and M. Ollier, a surgeon much younger, but of great merit, director of the Lyons Hospital, for his applications of the first method of purely sub-periosteal treatment.

Prize for Unhealthy Occupations in the Arts.—M. Galibert, for his respiratory apparatus, by means of which any one can enter into the most mephitic atmosphere. Most honourable mention, with 40*l.* gratuity from the Montyon fund. We sincerely congratulate him.

The Bréant Prize.—Nature and treatment of cholera. 80*l.* to Messrs. Legros and Goujon, for their experimental researches on the cholera, its transmission, and epidemic nature during 1866; 48*l.* were awarded to M. Thiersh, for his experiments upon the toxic principles of choleraic dejections; 32*l.* to M. Baudrimont, for his analyses and observations relative to epidemic cholera; the same sum to M. Worms, for his work on the propagation of the cholera, and the means of restraining it. Honourable mention to M. Lindsay for his experiments on the transmission of the disease by the emanations from the clothing and the dejections of cholera patients.

The Cuvier Prize was awarded to M. Baer, of St. Petersburg, for his collection of researches on embryogenic and other zoological matters.

The Jecker Prize was awarded to M. Augustus Cahours, for the precision and exactitude of his experiments on the compounds of antimony, tin, &c., with the carbides of hydrogen in the category of the ethyls, methyls, &c.; also upon the densities of vapours which do not act as gases, except at temperatures far beyond their boiling point.

Barbier Prize.—20*l.* to M. Lailler, for his researches on native opium; the same sum to M. Debeaux, for his essay on the pharmacy and materia medica of the Chinese.

Godard Prize.—40*l.* to Drs. Aimé Martin and Henri Leger, for their researches on the anatomy and pathology of the female organs.

Savigny Prize, founded by Madame Letellier, was awarded to M. Leon Vaillant, for his researches during his voyage in the Red Sea during the year 1864.

Desmazieres Prize.—M. Roze, for his delicate and skilful researches on the antherozoides of a great number of cryptogamic plants and their theory of reproduction.

Thore Prize.—M. Fabre, Professor at the Lyceum of Avignon, for his memoir on his new observations upon the hypermetaphose and habits of the meloid class of insect.

Thus our Academy of Sciences has awarded nearly 4000*l.* worth of prizes for the encouragement of scientific progress in all its forms. On this subject it occupies a position quite exceptional, and not to be compared with any other scientific body of the old or new world.

NOTICES OF BOOKS.

A Dictionary of Photography. Edited by Thomas Sutton, B.A., editor of "Photographic Notes," and George Dawson, M.A., Lecturer on Photography, King's College, London. London: Sampson Low, Son, and Marston. 1867.

Now that photographic processes, lenses, and chemicals have multiplied to an extent that makes a practical acquaintance with the whole of them almost an impossibility, such a work as the present becomes a necessity to photographers, who would otherwise, when requiring information upon any particular subject, have to wade through a complete set of the photographic journals, with, after all, only a chance of finding what is wanted. With the assistance of this dictionary any information connected with photography may be at once obtained, and where space will not permit of many details, the reader is referred to other works where the subject is treated at length.

In a limited space it is, of course, difficult to confine each subject to the dimensions prescribed for it by its comparative importance, and in such a matter considerable latitude must be allowed to individual opinion; still we cannot help thinking that a little more brevity in some of the subjects would have been advisable, as it would have left space at liberty to be bestowed where more details were really wanted. In a work like this, for example, no one would look for a regular treatise on the principles of optics, or for the formulæ according to which the different curves of lenses are calculated, while the connexion of polarised light with photography is certainly not easy to discern. In short, we think that in a future edition the usefulness of the book might be materially increased by condensing

or erasing much of the portion relating to the optics of photography, and replacing it by additional details in the various processes, more particularly in those that are at present imperfectly known to the majority of photographers, but which seem likely to play such an important part in the future of the science, such as Swan's carbon printing process and Major Russell's rapid tannin process on bromised collodion.

In the article on Lenses there is much information given that all photographers should be acquainted with, though unfortunately the formidable aspect of the diagrams and algebraical equations will deter many from reading it. The best landscape lens is said to be Ross's actinic doublet, while among single view-lenses the preference is given to the deep meniscus, by which a perfectly flat field may be secured. This property was discovered by Mr. Sutton about two years ago. Mr. Sutton's panoramic lens is favourably mentioned, but will hardly, we think, be much used, as it requires the negatives to be taken upon spherical bowls or cylinders of glass, and the picture when completed must be bent into the same form to give a correct representation of the view. The principle of Mr. Grubb's well-known aplanatic lens is said to have been tried and condemned by the late Mr. Andrew Ross five-and-twenty years ago.

A just tribute is paid to the beauty of the daguerreotype process, which has been so long and undeservedly neglected. We insert some of the remarks, with which we cordially agree, in the hope that attention may be again directed to this beautiful process:—

"A fine daguerreotype exhibits microscopic perfection of detail and perfect gradation of shades. Other processes, when compared with this, are coarse and imperfect in the results, and of all known methods of representing a natural object by photography, the daguerreotype process is the most perfect and scientific.

"A daguerreotype is permanent; the picture cannot be rubbed off the plate, the plate cannot be broken by accident, the picture will bear microscopic investigation. Other processes have their merits, but this is the triumph of the photographic art and a boon to science."

Advantages of Gas in Private Houses. A Handy-Book for Gas Consumers: telling them what to do and what not to do. By J. O. N. Rutter, F.R.A.S. London: Virtue Brothers and Co. 1865.

In this little book the advantages of gas for lighting private dwellings are fully set forth, the management of it explained, and all the objections that have been made to its use either denied or the means pointed out by which they may be removed. One of the objections frequently alleged against gas is the heat and closeness it produces in small rooms, but, as the author justly observes, the quantity of heat produced by gas or candles is in proportion to the amount of light they give. If, where two candles were enough, gas is introduced that gives the light of twelve, the ventilation that answered in the former case will naturally be insufficient, and it should either be increased or less gas consumed. Most of the other objections are explained equally successfully, and with proper management it is shown that the danger of fire is far less with gas than when candles are employed. A careful perusal of this pamphlet may reassure those who at present hesitate about using gas on account of the danger or unhealthiness that has been attributed to it.

How to get over a Difficulty.—We quote the following from the *Medical Mirror*:—"For our own part, we are inclined to say about science and the Bible what the Mussulman said with reference to his Koran:—If science agrees with the Bible, science is superfluous, and may be destroyed, and if science goes against the Bible, it is pernicious, and must be destroyed."

CONTEMPORARY SCIENTIFIC PRESS.

[Under this heading it is intended to give the titles of all the chemical papers which are published in the principal scientific periodicals of the Continent. Articles which are merely reprints or abstracts of papers already noticed will be omitted. Abstracts of the more important papers here announced will appear in future numbers of the Chemical News.]

Kunst und Gewerbeblatt des Polytechnischen Vereins für das Konigreich Bayern. November and December, 1866.

Dr. Jünnemann "*On the Conversion of Tallow into Adipocire.*"—Dr. Schödler "*On the Removal of Iron Rust and other Stains from Textile Fabrics.*"—Dr. Winkler "*On the Influence of Rusting on Weights;*" "*On the Purification of Graphite.*"

Journal de Pharmacie et de Chimie. January, 1867.

Lefort "*On the Tinctorial Use and Value of Buckthorn Seeds.*"—Bellamy "*On the Use of Permanganate of Potassa as applied to Estimate Organic Matter in Water: Estimation of the Carbon in such Organic Matter.*"—Guibourt "*On Garou Bark.*"—Bert "*On the Separation of the Salts of Strychnia by means of Phenic Acid.*"—Ricker: "*Ferruginated Cod-liver Oil.*"

NOTICES OF PATENTS.

Communicated by Mr. Vaughan, F.C.S., Patent Agent, 54, Chancery Lane, W. C.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

309. S. Plant and W. Tatton, Sutton, near Macclesfield, Cheshire, "An improvement in the manufacture of firelighters and artificial fuel."—Petition recorded Feb. 4, 1867.

250. E. V. L. Ebersburg, Montpellier Street, Knightsbridge, Middlesex, "A new or improved article of food for infants and invalids." Partly a communication from Baron J. von Liebig, Munich, Bavaria.—Jan. 30, 1867.

322. J. Ballonhey, Passavant, Haute Saone, France, "An improved process for vitrifying iron, cast-iron, and steel."—Feb. 5, 1867.

344. G. E. Pain, High Street, Camden Town, and C. Corroy, Dean Street, Soho, Middlesex, "Improvements in the preparation of oils for illuminating, lubricating, and other purposes for which they may be applicable."—Feb. 7, 1867.

425. J. Lamble, Southampton, "A new or improved composition for the coating and preservation of ships' bottoms."—Feb. 15, 1867.

Notices to Proceed.

2707. E. L. Simpson, Bridgeport, Fairfield, Conn., U. S. A., "An improved process for the preparation of india-rubber and kindred gums."

2709. A. Parkes, Birmingham, "Improvements in the manufacture of Parkesine, or compounds of pyroxylin, and in the production of imitations of ivory and pearl."—Petition recorded October 19, 1866.

3232. T. Gray, Wandsworth, Surrey, "Improvements in the preparation of bleaching materials or compounds." December 7, 1866.

3327. W. R. Lake, Southampton Buildings, Chancery Lane, "An improved mode of rendering paint uninflammable." A communication from J. B. Harris, Germantown, Kentucky, U. S. A.—December 18, 1866.

3359. C. Norrington, Plymouth, Devonshire, "Improvements in the treatment of substances containing phosphate of lime."—December 20, 1866.

3449. C. F. Flach, Call, Prussia, "Improvements in extracting silver from lead."—December 31, 1866.

2768. W. Weldon, Highgate, Middlesex, "An improved method of decomposing chloride of sodium and other compounds by means of steam."—Oct. 26, 1866.

CORRESPONDENCE.

Organic Matter in Water.

To the Editor of the Chemical News.

Sir,—In reply to the last letter of your correspondent "B. J. G." on the above subject, I would submit that the objections he urges, with somewhat unnecessary warmth, against my suggestions, in no way invalidate the latter, being founded partly on a misconception of the object they were intended to serve, partly upon purely theoretical considerations.

Thus, with regard to the first of them, I must remind him that the question proposed was not the identification of "fresh albumen," but that of animal sewage, to which it is obvious that the word "fresh," in the sense in which it is used by him, and upon which the whole objection hangs, is totally inapplicable.

Again, I do not think he can seriously mean to bring forward "vegetable albumen" as a probable source of error, if the detection of ammonia or nitrates in a water be accepted as conclusive evidence of the access of animal sewage to it; though the existence of this, in common with certain other azotised bodies, in small proportion in plants, was precisely the point to which I referred as interfering with the theoretical accuracy of such an inference. As regards his fourth objection, it is surely possible that sewage received in the upper portions of streams may become so diluted on its downward passage as at last to form only an infinitesimal ingredient of the water; and this is all that appears to be implied in the reports upon the metropolitan waters at which your correspondent takes exception.

The whole subject of the employment of permanganate of potash for the proximate estimation of organic matter in water, including the acknowledged defects of the process, has been so exhaustively treated by its author in the paper to which reference was made in my last letter, that it would be superfluous, as well as presumptuous, on my part to enlarge upon it here; but it may be remarked, in answer to the concluding observations of your correspondent, that oxalic acid is evidently employed in it only as a convenient standard of oxidation, while it is apparently adopted in the above-mentioned reports as an exponent of results which would otherwise be unintelligible to a large majority of readers, and of which, since their value is confessedly rather comparative than absolute, the original terms are necessarily of minor importance.

I am, &c.

Thos. P. Blunt.

Chemical Notices from Foreign Sources.

Vapour Density.—A. Cahours finds, from recent researches on acetic acid and bodies allied to it, that if their vapour densities, taken at intervals of 5°, are represented by curves, these curves gradually approach the axes of their abscissæ, and finally run parallel to them, continue parallel for some distance, and then give place to fresh curves. Acetic acid gives at 350° four volumes, and at 440° notably smaller numbers, with incipient decomposition; in the interval of 110°—115°, between its boiling point and the point at which four volumes are first observed, different numbers are obtained, corresponding to no definite degrees of condensation, whilst in an interval of about 200° it follows the laws of gases, and the numbers correspond exactly to four volumes.

Formic acid, and the compounds of hydrocarbons with hydracids, possess, in truth, but one molecular grouping corresponding to four volumes, for the molecular groups represented by eight volumes, which are obtained at higher temperatures, are no longer in relation to the original molecules, but are referable to dissociation.

He asks what are the grounds for the assumption that the molecules of all bodies must necessarily give four vapour volumes, and remarks that ammonic cyanide, in which dissociation does not occur even at 1200°, gives at 100° numbers corresponding to eight volumes. So also phosphoric pentachloride, which boils at 160°—165°, gives at 170°—172° numbers far removed from four volumes. He concludes—1. That the molecule of a compound volatile body in the state of vapour corresponds to four or eight volumes; a molecular grouping corresponding to two or six volumes is possible, but is not yet proved to exist. 2. That a molecular grouping corresponding to three or six volumes does not exist in any bodies yet examined; for determinations made at temperatures 5° higher or lower than the points at which the numbers corresponding to such groups are obtained give different numbers.—(*Comptes R.*, lxiii. 14.)

Vapour Density.—Deville considers that the objections which many chemists have to admit that the equivalents of elements and compounds correspond to one and eight volumes, being grounded on analogies, are supported by little better than gratuitous hypotheses. He has, in conjunction with Troost, taken the vapour density of NH_4I,HgI at 350° and 440°, and obtained the numbers 6·49 and 6·38, the density calculated for eight volume being 6·44.

He fears lest, under the cloak of theory, vague ideas be introduced into chemistry, to the exceeding detriment of the science, and he concludes with the remark that, unless we make use of definite expressions and dismiss assumptions of unknown causes from our speculations, we shall be in danger of falling into the vagueness of mysticism.—(*Comptes R.*, lxiii. 18.)

Cyanogen, Chlorine Compounds of.—A. Gautier recommends the following method of preparing solid chloride of cyanogen without recourse to the liquid chloride:—A slow current of chlorine is passed through a solution of one part of cyanhydric acid in four parts of anhydrous ether. Viscid drops form on the sides of the vessel, and after twenty-four hours become crystalline groups. He finds that the solid chloride melts at 145° and solidifies at 130°. The bromide may be prepared in like manner.—(*Bull. Soc. Chim. Paris*, v. 403.)

Respiration, Experiments on.—Max von Pettenkofer and Karl Voit have made further experiments in the respiration apparatus described (*Ann. Chem. Pharm.*, Supp. 2), and find that more oxygen is absorbed during sleep than during the day, whilst less carbonic anhydride is given off by night than by day; during labour a man exhales much more carbonic anhydride and water than during repose (not sleep), but the amount of oxygen absorbed is the same on both days; however, during the night following the working day, a much greater than the normal quantity of oxygen is absorbed. It appears from these facts that the oxygen absorbed during sleep is stored up in the body for several hours, where it probably assists in a process of slow oxidation of the nutriment introduced into the body during the following day. Even during days of rest, the quantites of carbonic anhydride and water eliminated are greater than those which correspond to the quantity of oxygen absorbed during those days. The same quantities of carbonic anhydride are exhaled during the nights following working or resting days, and evidently result from the muscular movements made during sleep. In the night following working days, there is a great increase in the water given off by respiration and perspiration, serving, perhaps, to cool the muscles heated by labour.

The same quantity of urea is secreted in working as in resting days, showing that the work of the muscles is

performed without an increase in the decomposition of albuminoid substances.

These results confirm those obtained by Henneberg in 1865 when experimenting on oxen.

Experiments were also made on men suffering from diabetes mellitus and leukæmia lienalis. The patients always had excellent appetites, but, though fed on the most nutritive meats, were totally devoid of strength, nor were they refreshed by sleep. The same differences between the oxygen absorbed and the carbonic anhydride given off by day and night were observed in this case as were noticed when experimenting on healthy subjects.—(*Akad. München*, November 10, 1866.)

Carbonic Sulphides (C=12; O=16).—O. Loew describes a body C_4S obtained by acting upon acetic acid with phosphoric persulphide; it is insoluble in carbonic bisulphide, but dissolves with production of a red colour in concentrated sulphuric acid.—(*Zeitsch. Chem.*, N.S., iii. 20.)

Specific Heat of Graphite.—V. Regnault has determined the specific heat of several specimens of natural and artificial graphite. Graphite from Canada, No. 1, gave a mean number ·19866; from Canada, No. 2, mean ·20198; from Canada, No. 3, mean ·19113; from Siberia, mean ·19879. Graphite from gas retorts, after being heated white-hot, gave mean ·1968; the same kind of graphite, after being heated in a current of chlorine, gave ·2000, and that from Canada No. 3, after like treatment, gave ·1977. Hard burnt clay gave ·1940; therefore the ash in graphite (consisting principally of clay) has no appreciable effect on the results obtained. (*Ann. Chim. Phys.* [4], vii. 450.)

H. Kopp remarks on the above numbers that they are obtained by immersing the graphite heated up to 100° in the water of the calorimeter; that graphite is porous; therefore the heat given off by the water as it enters the pores of the substance reappears in the final result of the experiment. Regnault's numbers are higher than those obtained by Kopp.—(*Ann. Chem. Pharm.* cxii. 121.)

The Behaviour of some Minerals at a high Temperature.—Dr. L. Elsner has heated a great variety of minerals and other rock constituents in a porcelain furnace to an estimated temperature of 2500° to 3000°, and finds in general that silicates containing the alkaline metals, or iron, are much more fusible than those which contain much alumina, or no iron; with the exception of obsidian, all the rocks experimented upon, even those of volcanic origin, presented, after heating, totally different characteristics from those which accompany them in nature; the crystalline varieties became compact and semi-fused; therefore they must have been produced in nature under different conditions from those of his experiments. The conversion of pumice into an obsidian-like body is especially interesting. After heating, the rocks experimented on showed lower specific gravities.—(*Journ. prakt. Chem.*, xcix. 262.)

Tannic Acids.—Dr. R. Wagner distinguishes two varieties of tannic acid—the "pathological," in gall-nuts, ordinary tannin; the "physiological," in oak-bark, divi-divi, sumach, &c.—and gives the characteristic reactions of each variety; the physiological kind is alone fit for tanning purposes. He has examined all the known methods for the quantitative determination of physiological tannic acid, and, finding them all more or less unsatisfactory, proposes the following one, not indeed as perfect, but at least tolerable:—To a standard solution of neutral cinchonic sulphate in water, rosanilinic acetate is added in very small quantity; this solution is added from the burette to the tannic acid solution until the liquid above the precipitate of cinchonic tannate is coloured pink, which indicates the end of the reaction. —(*Journ. prakt. Chem.*, xcix. 294.)

Lactose.—Dr. Fudakowski, by acting upon pure sugar of milk with dilute sulphuric acid, separated it into two kinds of sugar; both are capable of undergoing fermentation, although the one kind, which has been before described by Pasteur, and crystallises in hexagonal plates, ferments more rapidly under like conditions than the other variety, which crystallises in right prisms, is less soluble in alcohol, and has a less sweet taste. Both turn the plane of polarisation to the right.—(*Med. Chem. Untersuchungen aus dem Lab. Tübingen*, 164.)

Curarine.—Dragendorff, to avoid the possible decomposition of the phospho-molybdate in the preparation of this body, proposes to evaporate to dryness, with the addition of glass powder, the alkaline solution from which the strychnine has been separated, extract the residue with alcohol of 95 per cent., add glass powder to the extract, again evaporate to dryness, take up with water, again evaporate to dryness, and finally extract the alkaloid with alcohol, which leaves it as a pale yellow residue.—(*Pharm. Journ. Russia*, 1866, 158.)

MISCELLANEOUS.

Chemical Society's Dinner.—The Secretary will be glad to hear at once from those Fellows who propose to attend the dinner on the 27th inst. and have not yet replied to his invitation, so that the necessary arrangements may be made.

Universal Pharmacopœia.—At the last meeting of the Pharmaceutical Society the Chairman stated that he had received an invitation to send delegates to Paris in August next for the purpose of compiling a universal Pharmacopœia. It seemed to be the general impression of the leading members present that it would be impossible to assimilate the whole of the Pharmacopœias.

Assay of Tannin.—Tannic acid, or tannin, is now employed in manufacture. Although no fraud has been effected, yet, by reason of the high price of this product, it is well to be able to test it easily. Tannin being soluble in ether, 1 gramme of tannin placed in the testing-tube, and covered with 10 grammes of ether, ought entirely to dissolve in it.—*Moniteur Scientifique.*

Composition and Quality of the Metropolitan Waters in February, 1867.—The following are the Returns of the Metropolitan Association of Medical Officers of Health:—

Names of Water Companies.	Total solid matter per gallon.	Loss by ignition.*	Oxidisable organic matter.†	Hardness.	
				Before boiling.	After boiling.
Thames Water Companies.	Grains.	Grns.	Grains.	Degs.	Degs.
Grand Junction	20·29	1·96	1·35	13·0	5·5
West Middlesex	20·00	2·00	1·81	13·0	5·0
Southwark & Vauxhall	20·00	2·14	1·92	13·0	5·0
Chelsea	20·17	1·75	1·18	13·0	5·0
Lambeth	20·47	1·99	1·61	13·0	5·0
Other Companies.					
Kent	27·41	1·25	0·08	16·5	9·0

* The loss by ignition represents a variety of volatile matters, as well as organic matter, as ammoniacal salts, moisture, and the volatile constituents of nitrates and nitrites.

† The oxidisable organic matter is determined by a standard solution of permanganate of potash, the available oxygen of which is to the organic matter as 1 is to 8; and the results are controlled by the examination of the colour of the water when seen through a glass tube two feet in length and two inches in diameter.

HY. LETHEBY, M.B.

Electric Lamp for Miners.—Several attempts have been made in France to supply the electric light to the miner's lamp, and the following is a description of such lamp now made by M. Gaiffe, a philosophical instrument maker of Paris:—M. Gaiffe has availed himself of the curious effect produced by nitrogen and glass of uranium, which give the complementary colours rose and green, which united produce a white light rather more intense than that obtained by means of carbonic acid. M. Gaiffe's apparatus consists of a small bobbin, a pile, and a Geissler's tube, shown in the accompanying cut; the spirals T within the tube are formed of uranium glass, within which is pure and perfectly dry nitrogen. The spirals are contained within a tube of ordinary glass from which the air is exhausted, and the points are to be seen at the ends of the tube. The whole of this apparatus is enclosed in a very strong outer glass case E to prevent accidents; the mouth of the outer case is closed by means of an india-rubber cap C, through which the wires R, R pass, and these are covered with gutta-percha. The pile and bobbin are contained in a small box which is strapped knapsack-like on the miner's back, the conductors passing one beneath each arm. The pile is so enclosed as to allow the miner to assume almost any position without spilling the solution, and will work for eight or ten hours. The whole apparatus weighs seven pounds, and its present price is seventy francs. A similar lamp is used for under-water work; only in the latter case the conductors are longer, and the apparatus has a counterbalance to prevent its descending with too great rapidity.—*The Engineer.*

On Navassa Guano.—This material, which is found on the Island of Navassa, situated in the Caribbean Sea, is not, like the Peruvian guano, a product of birds, but a mineral, differing from apatite by not containing chlorine and fluorine, and by containing organic matter. A company at Baltimore, U. S., works the quarries, and subjoined is an analysis of the raw material by Dr. Ulex, at Hamburg:—Moisture, 1·6; organic matter, 10·4; SO_3, 31·2; lime, 34·5; CO_2, 3·3; alumina and peroxide of iron, 19·0: total 100·0. It is stated to be imported into England.—*Polytechnisches Centralblatt.*

Preservation of Meat.—On Friday last we were invited by Professor John Gamgee to meet the sub-committee of the Society of Arts on meat supply, and other persons interested in the question, at the Albert Veterinary College, Bayswater, for the purpose of witnessing the whole operation of preserving meat according to a process lately patented by Professor Gamgee. We are not at liberty at present to divulge the whole of the process, but we may state that, by a novel and apparently painless method of slaughter, the cattle are caused to undergo the preliminary pickling stage whilst *in articulo mortis*, and by this means the meat is endowed with the power of resisting decomposition and preserving its fresh pink colour for a period of five or six weeks. The completion of the process consists in packing the joints (containing bone, fat, skin, &c., just as they would be supplied by the butcher to customers) in an iron case, exhausting the air from it, and then filling up with a gas or vapour; after which the case is soldered down, and the preservative process is complete. The visitors saw an ox and a sheep killed by the new process, and then witnessed the process of packing, exhausting, filling with antiseptic vapour, and soldering down; the joints in the latter case having been cut from an ox and a sheep which had been killed on the previous Saturday in the presence of Dr. Miller and other leading chemists. Several of these cases were carried away by Mr. Le Neve Foster, Secretary of the Society of Arts, for the purpose of exposure for some time in artificially-heated rooms and subsequent examination. So little is the appearance or taste of the meat affected by the new method of killing, that, at Christmas last, joints of meat from animals so slaughtered were in great request at a butcher's in the neighbourhood, where they had been hung up experimentally. The length of time which meat so preserved will retain its fresh colour, appearance, and taste, has not been ascertained, but we examined a sirloin of beef killed early in November last, and were unable to distinguish it from fresh meat. The process is remarkably simple and easy to be carried out on the large scale. Experiments have now been in progress for a sufficient time and on a sufficiently large scale to test its practicability, and we believe that before long arrangements will be concluded for carrying Professor Gamgee's valuable discovery into operation in South America, Australia, as well as on the continent of Europe.

The Chemistry of Stock Feeding.—In the course of a lecture on the above, delivered to the Newbury Farmers' Club, Mr. Warrington, of the Royal Agricultural College, Cirencester, has given details of some original researches of great practical value, with an outline of the chemistry and physiology of nutrition, respiration, and muscular force. The question of obtaining the maximum mechanical work from an animal by judicious feeding was left untouched—we hope, only to be exhaustively treated on a future occasion. The following remarks apply to food as a means of increasing the animal frame. In the sheep are the following constituents:—

	Store Sheep.	Fat Sheep.	Very Fat Sheep.
Nitrogenous substances .	15·7	13·0	11·5
Fat	19·9	37·9	48·3
Mineral substances . .	3·4	3·0	3·1
Water	61·0	46·1	37·1
	100·0	100·0	100·0

It will be seen that as the fat progressively increases the nitrogenous substances and water decrease. The more rough and practical statement is—

Nitrogenous substances = muscle
Fat = fat
Mineral substances = bone,

being sufficient for stock-feeding considerations. The fat and muscle both increase, this increase ultimately having a much smaller proportion in a fat animal than in a lean one. Suppose the sheep weighs 100 lbs., and after fattening weighs 150 lbs., what is the composition of the 50 lbs. put on? Increase of a sheep while fattening—

Nitrogenous substances . .	7·5
Fat	63·0
Mineral substances . . .	2·0
Water	27·5
	100·0

The increase in other animals is very similar. The proportionate increase by bulk of the muscle will be different from that by weight, by reason of the association of the water with it. The animal economy is shown to be de-

structive, and the foods commonly used to supply aliment for animals have the following composition:—

	Swedes.	Meadow Hay.	Barley.	Beans.
Water	89·0	16·0	16·0	16·0

How do these percentages determine the fattening of an animal? Take an animal not increasing in weight, what purposes does its food serve? 1. Renovation of tissue; 2. Production of muscular force; 3. Production of heat. To give an idea of the second series' demands, we must note that a vast deal of muscular work is done within the body. It has been calculated that the work of the human heart in one day would suffice to raise its own weight ninety miles, other muscles acting to preserve the various positions of the body. In the case now considered the whole of the food will be consumed in supplying these three requisites; all the nitrogen not so used requires evacuation as manure—is not stored up. The excess of fat is stored up. Mr. Warrington remarked that "if the chemist cannot imitate the constructive powers of a plant, neither can he imitate the destructive powers of an animal; he can only observe and admire." Excess of starch, sugar, &c., cannot be stored as such; they are converted into fat and so stored. The following experiment is interesting:—Two pigs from the same litter, and of almost equal weights, were taken; one was killed, and found to contain 22 lbs. of fat. The other was fed for ten weeks longer, and then killed; it yielded 78 lbs. of fat: 56 lbs. of fat had thus been stored up in the ten weeks; the food of the pig during this time had, however, contained only 14 lbs. of fat; 42 lbs. had thus been actually formed by the animal. It is possible, also, that nitrogenised food may form fat; as a result where an excess of nitrogenous food is supplied, a portion is stored up as muscle, wool, &c., while the excess of sugar and starch is converted into fat. It is important to remember that it is only the excess of food which is stored up as increase. Chemical calculations have likewise shown that two and a half parts of starch are about the smallest quantity from which one part of fat could be produced; two and a half is thus said to be the "starch equivalent" of fat. As would be expected, the manure from fattening animals is most valuable; about 90 per cent. of the nitrogen in the food appeared in the manure; the more nitrogenous the food, the more valuable the manure. In liberal feeding a larger proportion of the food is excess; liberal feeding is thus true economy. Fattening is most economical when done in the shortest time. An ox weighing 1000 lbs. or more has through its whole life to be kept at a temperature of about 98° Fahr. by the combustion of food, which costs the farmer a good deal, but as thus consumed makes no return; the sooner the animal can be made prime, the smaller is this expense. Experiments at Rothamsted have taught us that, even when an animal is fattening under favouring circumstances, one-half its food is consumed to supply heat, &c., and does not minister at all to the formation of increase. The whole of these considerations show that for the farmer to judge what is really the cheapest food in different states of the market, he must know the chemical composition of foods. We hope with Mr. Warrington that the time will not be far distant when farmers will be the philosophers that theoretically they should be.

On Solid Hydride of Phosphorus,* by M. Rudorff.—On dissolving biniodide of phosphorus in water, there is deposited, especially with the aid of heat, a yellow powder, which has hitherto been considered as more or less modified phosphorus. According to M. Rudorff, this powder is solid hydride of phosphorus, possessing all the characteristics which MM. Leverrier and P. Thenard have assigned to this compound. It is obtained in the proportion of about 2 per cent. of the biniodide of phosphorus employed, the yield being the same with hot as with cold water; however, with hot water the yellow is more decided. The author considers this the simplest and most expeditious way of obtaining pure hydride of phosphorus.

ANSWERS TO CORRESPONDENTS.

*** All *Editorial Communications* are to be addressed to the Editor, and *Advertisements* and *Business Communications* to the Publisher, at the Office, 1, Wine Office Court, Fleet Street, London, E.C. *Private* letters for the Editor must be so marked.

J. Y. E.—Use caustic soda instead of potash.

Electro wishes to know the best and simplest method of coppering zinc by electrolysis. We know nothing better than the cyanide solution kept hot during the process.

Fittetienne.—We believe that no experiments have been yet published on the subject. Such a series would, however, be of considerable value at the present time.

Professor M.—Lithium is easily prepared by electrolysis of the fused chloride. It cannot be obtained in the same manner as potassium or sodium, owing to its non-volatility.

Rangoon Oil.—A correspondent would be glad to know the distinctive names and source of Rangoon oil, with tests and market price. The oil in question is used in the Government stores for greasing rifles and preserving them from rust.

W. Bell.—There has not been any work recently published containing the information you want, but valuable papers on the distillation of coal tar are plentifully scattered through scientific publications. Consult the several articles in Watts's Dictionary for the latest results.

M. James.—The alloy of copper 11, zinc 2, has the composition of "Dutch leaf gold." This is one of the most malleable alloys known, leaves of it having been beaten out to less than the fifty-thousandth of an inch in thickness. The other alloy—viz., copper 16, platinum 7, zinc 1—has the colour of 16-carat gold, and resists the nitric acid test.

A Constant Reader.—The rule to be adopted in these cases is to append the final *e* only to basic bodies, and to spell neutral substances without the *e*. Thus we write benzol, paraffin, &c.; aniline, strychnine, &c. This rule is, however, as often violated as observed.

J. Q.—Phosphorus dissolved in chloroform will be a more pleasant solution than when bisulphide of carbon is the solvent. Sufficient phosphorus will be present to ignite when the liquid is evaporated on paper.

Prussian Blue.—"Chromium" is requested to send his address to the office.

J. F. Dickson.—In our next.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On the Decomposition of Sulphate of Lead by Ammoniacal Gas, by George Farrer Rodwell, *F.C.S.*

Perfectly pure sulphate of lead was heated in a current of dry ammoniacal gas, and the products of the reaction were found to be subsulphide, and sulphide of lead, water, sulphite of ammonium, and free nitrogen.

The ammoniacal gas employed for the decomposition was washed by passing through a saturated solution of ammonia, and through two bottles containing a saturated solution of caustic potash, and it was dried by passing through tubes filled with small lumps of fused caustic potash. To the last of these tubes a piece of combustion tubing containing a weighed quantity of the sulphate was connected, and it was heated by means of a four-jet Bunsen burner. The sulphite of ammonium was retained by a thick plug of asbestos previously boiled in water, and strongly ignited; the water was collected in a tube filled with fused caustic potash, and the nitrogen was collected in a graduated tube standing over water, and afterwards measured.

The following are the most concordant results of a number of determinations:—

Pb_2S+PbS	H_2O
75·7330	18·7223
75·8426	18·2543
75·7763	18·8295
75·7662	18·6336
$(H_4N)_2SO_3$	N
10·8237	10·7673
10·3134	10·9921
10·9090	10·3538

Mean Results.

Pb_2S+PbS	75·7795
H_2O	18·6099
$(H_4N)_2SO_3$	10·6820
N	10·7044
	115·7758

From the above we see that the decomposition is effected by the action of 15·7758 parts of H_3N upon 100 parts of $PbSO_4$.

The above figures closely correspond with the following equation:—

$$7PbSO_4+20H_3N=$$
$$=3PbS+2Pb_2S+22H_2O+2[(H_4N)_2SO_3]+N_{16}.$$

which requires

Pb_2S+PbS	75·8603

On the Determination of the Quality of Silver prepared by different Methods, by Professor Stas.

(Continued from page 111.)

After having heated to dull redness a certain quantity of each specimen of silver that I wished to compare, I weighed in the air 9·99943 grs. of each by means of platinum weights, which is equivalent to 10·0000 grs. of this metal in vacuo. I dissolved each assay in pure nitric acid of a specific gravity of 1·24. The solution was accomplished by placing the flask in a hot-air bath. To prevent the silver being carried off by the gases produced, I inclined the flask 40 or 45 degrees, and by means of a stopper of vulcanised india-rubber, desulphurated by a boiling solution of hydrate of sodium, I fitted on a bent tube having a bulb in the descending branch. The end of the tube dipped into the water contained in a little flask. The bulb was large enough to contain the liquid for washing the gas. I kept the temperature so low that the solution took place slowly—an absolutely indispensable condition when it is required to prevent the solution of silver being carried over by the disengaged nitric oxide.

The silver having been dissolved and the flask cooled, I inverted the tube so as to pour into the flask the washing water that had ascended into the bulb, and I then washed the matrass and the tube with pure water, taking care to add the liquid to the contents of the flask.

All the flasks were then carried into the dark room where the assay apparatus was fitted up. *All the surfaces in this dark room are covered with three layers of lump-black held in suspension by gelatine.* The room was lighted by gas, and a screen of yellow glass interposed between the flame and the objects which were to be lighted, and which are decomposed by white light.*

The flasks being surrounded by an envelope of india-rubber, I poured into each, under absolutely the same conditions of temperature, the liquid produced by the emptying, twice repeated, of the measurer filled with saline solution up to the o division.

In order to be certain that the temperature of the liquid contained in the measurer was exactly that of the bath that surrounded it, I took care to wait until the level in the capillary tube remained constant, as is the case with the liquid in a thermometer placed in a medium at a constant temperature; *it is for this reason that the calibrated capillary tube was joined on to the pipette.*

When I had closed the flasks, and shaken violently the liquid contained in them, I carried them successively into the *apparatus for titration*, in which I proceeded to examine the excess of silver or salt.

This apparatus is composed of a parallelopiped of wood 70 centimetres long, 22 broad, and 45 high, covered above with moveable boards, two of which have holes in the middle. Its interior is completely blackened, and separated into two compartments by a movable screen, furnished with a circular opening three centimetres in diameter. This opening allows to pass a cone of yellow light, proceeding from a spherical globe, which contains a solution of neutral chromate of sodium. Opposite the sphere is placed, at a suitable distance, a lamp of gas or petroleum (I have used both), the flame of which is so arranged that the brightest part of the luminous cone corresponds to the centre of the globe.

On the other side of the perforated screen is placed, likewise at a suitable distance, the flask containing the assay. I take care to raise or lower the flask, so that the surface of the liquid contained in it coincides exactly with the middle of the opening.

In examining the liquid either by the little sliding doors arranged in front of the apparatus, or by the little

* In mints, as in chemical laboratories, assays of the quality of silver take place in diffused light. *I venture to say that no exact determination is possible in this condition.* The comparative assays I have made leave me no doubt on this subject; still, the error that may thus be made does not sensibly influence the result, seeing the tolerably large limit within which it is given.

doors arranged at the side, we perceive that a section of a few centimetres only of the liquid is brilliantly illuminated, whilst the rest, together with the chloride at the bottom of the flask, is in complete darkness. The height of the illuminated section of the liquid depends upon the luminous cone, and the luminous cone depends both upon the diameter of the sphere and the relative position of the lamp and the flask with respect to the sphere. All turbidity, however slight, produced in the upper portion of the liquid by the formation of chloride of silver, is perceived; in fact, bodies suspended there become at once luminous. I have already shown, in my article of 1860, the appearance taken by the precipitated chloride of silver, according to the richness of the liquid in silver; I shall not revert to it. I will merely allow myself to repeat that, by means of this artifice, we can determine, in a few moments, a *twentieth of a milligramme* of silver in a litre of distilled water, and that, by waiting long enough (fifteen minutes), we can perceive and measure a *fiftieth* or even a *hundredth* of a milligramme in a quart of liquid, after having allowed to fall on its surface a solution of a chloride containing an equivalent quantity of chlorine. The smallest quantity of chloride of silver produced forms a kind of veil, which increases in thickness and brilliancy as the liquid added becomes mixed with that in the flask.

To determine the quantity of silver or of chloride of sodium not precipitated, I used normal solutions of pure salt and of silver. The measure I employed showed exactly *twenty drops* in a cubic centimetre of liquid. *One hundred thousandth* of silver was thus represented by *two drops*. Now, those who are sufficiently acquainted with the moist way know that *one* drop of normal liquid is enough to show the presence or absence of dissolved silver.

Here is the result of the assays of the silver prepared by different methods. I have added three assays of the silver prepared by Gay-Lussac's process, so as to show how powerless this method is to furnish the pure metal. I have, however, sufficiently noticed the fact of this impurity in my former work.

Quality of the Silver prepared by Different Methods.

Reduction from the chloride by means of charcoal and chalk; three treatments.	0·00000	0·0009	99·991

If we except the method of Gay-Lussac, we may admit that all the processes shown in my previous work, and those which I have described in this, when properly performed, furnish absolutely pure silver, provided we take care to submit the metal to a sort of refining by heating it to the boiling point in a lime crucible in the flame of oxyhydrogen gas.

† The silver experimented on is part of that which I assayed in 1857, and in which I found *directly* twenty-three hundred-thousandths of foreign matter, instead of twenty-five hundred-thousandths, as I now find.

Looking at the figures of the preceding table, the constancy of the results obtained from the same metal is noticeable. In the three series of determinations I had each time to renew the saline liquid, on account of the insufficiency of the capacity of the reservoir; but in each series it is the same chloride and the same silver, that obtained by electrolysis, that have served as a type of comparison. The results have been identical. We may, then, assert that, by operating under suitable conditions—which I have sufficiently pointed out—it is possible to seize the exact moment when the *complete elimination* of the dissolved silver is accomplished; there is no doubt that the method of the moist way, for the *comparison* of different silvers with each other, gives results almost mathematically exact.

When, for the determinations set forth in this work, I have had to measure the quantity of silver, or of chlorine, of bromine, or of iodine existing in a liquid in which I had formed either a chloride, a bromide, or an iodide of silver, I performed this measurement in conditions identical with those I have just described on the subject of the determination of the quality of silver, and took the same care in it. The results therefore deserve the same confidence.

After having shown the methods I employed to procure pure silver, I will now relate the means I employed to prepare the chloride of ammonium, to be used in the determination of the proportional relation of this metal with chlorine.

TECHNICAL CHEMISTRY.

The Theory and Working of Blast Furnaces, by Wm. Crossley, *F.C.S., Manager Ormesby Iron Works.**

(*Concluded from page* 124.)

Another point to which I will direct your attention is the utilisation of blast furnace gas, whereby most firms have been enabled to do away altogether with the use of coal either for stoves or boilers. Furnace gas, as I have stated before, is a mixture of carbonic oxide (carbon combined with only half the full quantity of oxygen it is capable of combining with), free nitrogen, and the carbonic acid driven off from the limestone. The greatest difficulty in dealing with it seems to be owing to its great bulk, and the impossibility from ordinary observation of telling when it is completely oxidised; and as from calculation it would seem that we have not yet succeeded in utilising all the heat it is capable of evolving, some easy means for determining the best way of burning the gas, so that it does not take a large portion of heat up the stack with it, or else escape without perfect combustion having taken place is to be desired. I have made the following calculation based on the units of heat evolved by the combustion of 1 lb. of carbonic acid and 1 lb. of coal.

Taking the average coke used in the district at 25 cwt. to the ton of iron made, and the make of iron at 250 tons per furnace per week, there will be produced 729 tons of carbonic oxide, 163 of which will be oxidised by the oxygen in the iron ore into carbonic acid, leaving 556 tons as evolved from each furnace per week. The above, when properly consumed, should do the work of 206 tons of coal. I am quite aware that this carbonic oxide is mixed, 1664 tons of nitrogen and 331 tons of carbonic acid, but as this should not enter the stack at a higher temperature than it leaves the furnace, it ought not materially to affect the result; but, for the sake of discussing the matter fairly, let us allow something for this. To reduce the quantity to 180 tons of coal as its equivalent per week, I am sure, is ample; and I ask, is the gas from each furnace in the best arrangement at present at work doing the work of 180 tons of coal? If not, what direction ought any experiments to take for more fully utilising the furnace gas? I have already said that the principal thing is the proper admission of air, and some means of doing this is what we most want. I submit the following as my idea of the matter. By taking into consideration the composition of furnace gas, the composition of atmospheric air, and the quantity of oxygen required to fully oxidise the carbonic oxide, I find—after making due allowance for the gas being expanded by heat—that rather under one part of atmospheric air is required for the proper combustion of three parts furnace gas; and hence, if the gas was not forced into the stoves or under the boiler by the back pressure in the gas main, this would be about the proper proportion between the air inlet and the gas inlet valves, and, corrected for the back pressure, I do not know if this will not be the best means of regulating it. This leads us to the next point—viz., the direction in which any further efforts made for the better working of blast furnaces ought to tend.

1. There is a still further increase in temperature of blast.

The advantages of increased temperature of blast pointed out by Mr. Cochrane, to which I have referred, are not the maximum of what can be obtained. There cannot be the slightest doubt but that a further increase still will lead to increased saving in fuel, to increased make of iron, and probably to improved quality of iron; for we must remember that the hot blast, by decreasing the quantity of fuel to a given result, also decreases the quantity of sulphur and other impurities passing through the furnaces. Dr. Clarke, at the Clyde Iron Works, found that increasing the temperature of the blast from atmospheric temperature to 600° F. reduced the sulphur passing through the furnace in a given time from 2·57 tons to ·72 ton. When we consider the injurious effect on iron of even a very small quantity of sulphur, this fact ought surely to be worth taking into consideration, especially as the decrease in sulphur also involves other two important results—viz., the furnace is able to carry a heavier load, and to work with less limestone, for it is well known that a large excess of limestone is used, and comes away in the slag, over and above what is requisite to flux the siliceous and earthy matter contained in the stone.

Theoretically, I think the decrease in fuel used in the furnace will at any rate be equivalent to four times any fuel used outside for heating the blast until a temperature of blast is attained equal to the temperature of the furnace itself. There are, of course, many other things besides temperature to be considered, which may ultimately neutralise in other ways the good to be gained by very high temperatures; but I think we may safely aim at a much higher temperature than is at present obtained.

Lastly, knowing the great loss of heat we suffer by burning the coke into carbonic oxide, ought we not to consider if some other form of furnace will not answer much better, and have the effect of enabling us to form the higher oxide of carbon? The number of furnaces and modifications of furnaces that have been suggested with a view of doing this are innumerable—their name truly is legion—but past failure should not make us despond.

* Communicated by the author.

The numerous efforts that have been made in this direction show that something else is desired and believed in, and in the end we may succeed.

The following is, in my opinion, theoretically the proper form of furnace. The coke or coal is put into the hearth by means of a separate shaft, which shaft is so closed that at no time is there any current of gas through it. The blast is forced in through ordinary tuyeres, as at present, and the greatest intensity of heat is produced in the hearth where it is supposed to be most wanted. The hot gases pass into the main shaft containing limestone and ironstone, and after reaching a certain point it is ignited and kept in combustion by another jet of blast. By this means the gas is fully oxidised, and gives out its maximum of heat. The ironstone and limestone are tipped into the main shaft directly from the wagons in which they are received. The first effect on them will be to drive off the volatile matter and the carbonic acid, and as an excess of air can be forced into the upper tuyeres, the iron would probably be peroxidised. Lower down in the furnace the temperature of the ignited gas will probably be sufficient to melt the mixture; lower still, the iron in the melted mass would be reduced by passing through the atmosphere of carbonic oxide, and in the hearth itself would meet with the requisite carbon and intensity of heat to convert it into cast-iron. Although I say this is theoretically the proper form of furnace, and our efforts ought to tend to make it practicable, yet no one sees its present impracticableness, in some respects, more than myself, and I am prepared to criticise it as keenly as any one, but still I feel certain that if ever we do away with our present wasteful system of making iron it must be by some such furnace, and hence I draw attention to it, and ask for a thoughtful consideration of its claims.

On the Estimation of the Purity of Commercial Picric Acid, by John Casthelaz.

There were to be found in commerce last year, and, undoubtedly, are still, picric acids of all kinds and qualities. They are distinguished as—

Crystallised picric acid No. 1.	Picric acid in paste No. 1.
,, ,, No. 2.	,, ,, No. 2.
,, in massed crystals.	,, ,, No. 3.

In such conditions, what must the lowest scale of products be?

In order to avoid any confusion, would it not be preferable to prepare only two kinds of picric acid, both as pure as they can be obtained in an industrial manufacture—

Pure crystallised picric acid,

Pure pulvulerent picric acid?

I have adopted these two types; other manufacturers will do the same, and I am persuaded that before long they alone will figure in commerce.

I thought it would be convenient, both for the maker and the consumer, to have a small apparatus which would permit them, in a few moments, to assure themselves of the state of purity of a picric acid. I have therefore combined in the same box graduated tubes, mortar, pestle, scales, reagents, types, &c. This *ensemble* constitutes the picricometer of John Casthelaz.

Pure Picric Acid.—Picric acid is one of the most important derivatives of phenic acid; its scientific name of trinitrophenic acid shows, at the same time, its production and composition.

Obtained by the reaction of three equivalents of nitric acid on one equivalent of phenic acid, picric acid has for formula $C_{12}H_2(NO_4)_3,HO$.

Picric acid, as its name indicates, has a bitter and insufferable taste; more soluble in hot than cold water, it crystallises in flakes or into small prismatic crystals with a rhomboidal base, and of a beautiful pale yellow colour.

Picric acid, submitted to heat, partly melts and sublimes without alteration. Heated rapidly in the open air, it kindles without explosion and burns, leaving a carbonaceous residue; heated quickly, it detonates. Hydrochloric, nitric, and sulphuric acids are without action on it.

Picric acid unites with bases, and in general gives yellow salts, all more or less soluble. This will be spoken of more at length in the assay of picric acid by the wet way.

Lastly, picric acid dissolves easily in alcohol, in ether as well as in benzol.

It is on these latter properties of picric acid—on its, solubility in ether or in benzol—that the assay of picric acid, by means of the picricometer, is based.

Impurities of Picric Acids.—The impurities which are met with in commercial picric acids are of two kinds:—

1st. Accidental impurities.

2nd. Added impurities.

The first proceed from imperfection in the manufacture, the second from sophistication or additions.

Accidental Impurities.—They are due, it may be, to the agents employed in the manufacture of picric acid, to incomplete reactions, or to other causes which we are about to point out:—

1. If impure phenic acid containing neutral oils has been used, the picric acid will be accompanied by foreign nitro-compounds, which are distinguished by their insolubility in water.

2. If the reaction of nitric acid on phenic acid has not been complete, the picric acid may equally contain products insoluble in water. It will also contain nitrophenic or binitrophenic acids, which give, in tincture, a less clear and lively shade than picric acid.

3. If the picric acid in paste has not been well washed or well drained, it may contain water and nitrous acid.

4. If the reaction of nitric acid on phenic acid or certain oils which accompany it, has been too quick, or pushed too far by heat, the picric acid may contain oxalic acid. The case is rare. Oxalic acid, which is sometimes found associated with crystallised picric acid, may very often enter also into the category of added impurities.

The traces of sulphuric or hydrochloric acid which commercial nitric acids contain, disappear with washing, and attention need not be paid to them.

Additional Impurities.—These are the most important to discover and point out.

If, in phenic acid (manufactured from these two products, nitric acid and phenol), considerable quantities of sulphate of soda, nitrate of soda, chloride of sodium, alum, &c., are found, it is not very probable that these impurities proceed from the manufacture; they must have been directly added to the picric acid.

Principles of the Picricometer.—Pure picric acid being soluble in ether and benzol, the impurities described being little soluble or insoluble in these two solvents, a simple, prompt, and easy method of separating them follows. In treating picric acid with twenty times its weight of rectified ether, or with benzol in excess, picric

acid is dissolved; the impurities, oxalic acid, alum, salts, &c., remain insoluble.

The apparatus consists of a graduated tube contracted at the lower part. The tube which follows the contracted space is divided into four parts, each able to contain five grammes of ether, in the whole twenty grammes. The tube is stoppered to avoid the evaporation of the solvent. The manner of proceeding to test picric acid by ether, by means of the picricometer, is very simple. It is sufficient to take as uniform a sample as possible of the picric acid to be tested, to mix and pulverise the said acid, to weigh one gramme of it and place it in the picricometer, then to pour ether up to the fourth division, or a quantity of twenty grammes, afterwards to shake for a few moments. If the picric acid is pure, it will entirely dissolve in the ether; if the acid is adulterated, the insoluble impurities will settle in the lower part of the tube, and it will be easy to estimate their proportions.

If it is thought desirable to proceed more exactly, and to weigh the insoluble deposit, it is advisable to wash it with 5 grm. of ether, and to repeat this washing a second time in order to remove the last traces of picric acid. After this it will be easy to determine the nature of the insoluble deposit by the ordinary methods of analysis.

Test of Picric Acid by Benzol.—MM. Depouilly, to whom I had pointed out the mode of testing picric acid by ether, recommend the test by means of benzol in the two following cases:—

1st. When we wish to prove the presence of water, of liquid mineral acid (principally nitric acid), or a hydrated salt which may contain picric acid.

2nd. When we wish to estimate more certainly the quantity of oxalic acid.

Indeed, oxalic acid, although slightly soluble in ether, is completely insoluble in benzol. Benzol neither dissolving the soda salts formerly described nor alum, these latter remain insoluble, and are precipitated, as in the test by ether. Benzol is not so good a solvent of picric acid as ether, and it must be slightly warmed in order to facilitate solution. Under these circumstances it is better to operate only on a half-gram of the product to be tested, and to immerse the testing tube into warm water to aid the solution of the picric acid.

Test of Picric Acid by the Wet Way.—Picrates are, in general, very soluble. Picrates of soda, lime, barytes, iron, binoxide of mercury and of silver are very soluble.

The least soluble picrates are those of lead, protoxide of mercury, and potash.

The difference of solubility of picrate of potash and picrate of soda, furnishes an excellent means of discovering and distinguishing potash from soda salts.

Solution of picric acid, poured into a solution of a salt of potash, immediately gives a yellow precipitate of picrate of potash.

Solution of picric acid may easily be tested for sulphuric, oxalic, and hydrochloric acid, by adding to it solution of picrates of baryta, lime, and silver.

A picric acid, pure by these reagents, may still contain nitrates, but these salts will be revealed by the test with ether by means of the picricometer.

The results obtained by the wet way are thus useful as a control to the indications of the picricometer, and when these modes of experiment are better known and adopted, commercial picric acids will no longer be liable to contain these additional impurities, which it is of so much importance to the consumer to discover and remove.

PHYSICAL SCIENCE.

On a Magneto-electric Machine, by* W. Ladd.

In June, 1864, I received from Mr. Wilde a small magneto-electric machine consisting of a Siemens' armature and six magnets. This I endeavoured to improve upon, my object being to get a cheap machine for blasting with Abel's fuzes. This was attempted by making one with circular magnets and a Siemens' armature, revolving directly between the poles, the armature forming a part of the circle; with this I could send a very considerable power into an electro-magnet, &c. It was then suggested to me by my assistant that if the armature had two wires instead of one, the current of one being sent through a wire surrounding the magnets, their power would be augmented, and a considerable current might be obtained from the other wire available for external work; or there might be two armatures, one to exalt the power of the magnets, and the other made available for blasting or other purposes. Want of time has prevented me carrying this out until now; but after the interesting papers of C. W. Siemens, F.R.S., and Professor Wheatstone, F.R.S., were read last month, I have carried out the idea as follows:—Two bars of soft iron, measuring $7\frac{1}{2}$ in. × $2\frac{1}{2}$ in. × $\frac{1}{2}$ in., are each wound round the centre portions with about thirty yards of No. 10 copper wire, and shoes of soft iron so attached at each end that when the bars are placed one above the other there will be a space left between the opposite shoes in which a Siemens' armature can rotate. On each of the armatures is wound about ten yards of No. 14 copper wire, cotton-covered. The current generated in one of the armatures is always in connexion with the electro-magnet; and the current from the second armature, being perfectly free, can be used for any purpose for which it may be required. The machine is, altogether, rudely constructed, and is only intended to illustrate the principle; but with this small machine three inches of platinum wire ·01 can be made incandescent.

FOREIGN SCIENCE.

(From our own Correspondent.)

Paris, March 19, 1867.

The experiments on the electric light commenced on board the *Jerome Napoleon* yacht, under the direction of M. Georgette Dubuisson, captain of the frigate, and with the concurrence of M. Auguste Berlioz, director of the "Alliance" Company, have already given satisfactory results, especially as regards the possibility of avoiding collisions at sea, the cause of the loss of so many vessels. Besides the ordinary lighting-up apparatus, trials will shortly take place with light condensers, by the aid of which M. Louis d'Henry, demonstrator of physics at the Faculty of Sciences at Lille, was the first to put in use, and thus resolve, the following problem:—Being given a luminous point, *to contrive an apparatus which receives on its surface all the light emanating from that point, and directs it towards a position in space.* The condenser which is to be tried at Havre is composed of an ellipsoid of revolution, by means of which the light placed in one of the foci undergoes three reflections, and is projected sixteen times more intense than the direct pencil of rays. We can thus comprehend, in operating with the electric light equal to 100 or 200 gas burners, the effect that would be

* Communicated by the author, having been read before the Royal Society, March 14, 1867.

produced by sixteen times this light directed and convergent on a given point.

A company has been formed in Paris by the firm of Jos. de Susini and Co., with a capital of 80,000*l.*, for the general fabrication of oxygen gas by the process of M. Archereau. This process consists in the decomposition of sulphuric acid by heat or by special apparatus invented and patented by M. Archereau. The result of the decomposition is a mixture of oxygen and sulphurous acid; the latter is separated either by chemical absorption or by the compression of the two gases, causing the liquefaction of the sulphurous acid, which is allowed to escape by a stop-cock placed in the lower part of the recipient. This acid is newly converted into sulphuric acid by its injection into leaden chambers. With 11 kilogrammes of sulphuric acid at 60° a cubic metre of oxygen is formed. The conversion into sulphuric acid of the sulphurous acid proceeding from the decomposition would cost about 25 centimes, and the cost per cubic metre of oxygen gas thus produced would not exceed in any case 85 centimes. The fact upon which M. Archereau founds the enormous profits of the company is as follows:—The illumination, resulting from the combustion of two cubic metres of common gas and one cubic metre of oxygen, is equal in intensity to that of plain air combustion of sixteen cubic metres of ordinary bicarburetted gas. The former, two metres of gas and one of oxygen, would cost at most 1 fr. 45 c.; the second, sixteen cubic metres of gas, at the Paris price of 30 centimes the cubic metre (about 7*s.* the thousand feet), 4 fr. 50 c. There remains, then, a difference of 3 fr. 35 c. to be shared between the consumer and the producer of the superoxygenated gas for each sixteen cubic metres of gas consumed at the present day in Paris.

Nothing proves to us yet that the production of oxygenated gas by the decomposition of sulphuric acid or even sulphate of lime and the liquefaction of the sulphurous acid gas, brought back again to the state of sulphuric acid, is an industrial operation as easy and as economical as the prospectus, which we have before us, states. But it is certain, for it has been tried on a large scale at Sarrebruck, that the process of Messrs. Tessié de Mothay and Maréchier, of Metz—the superoxidation of the manganate of soda by a current of hot air, and the deoxidation of the permanganate by a current of steam—give all the excellent results expected. Each kilogramme of manganate gives off 85 litres of oxygen gas; the loss in each operation is almost nothing, and the price of each cubic metre of gas does not exceed half a franc. In a few days the apparatus of our friends will be installed in the Champ de Mars, on the grounds of the Exhibition, in a laboratory quite close to our lecture-hall. During the whole of the Exhibition they will work so as to furnish five cubic metres of gas per day, which will be partly utilised for the illumination of our hall by admixture either with the common gas or with the gas derived from the spontaneous contact of the air with the essences of petroleum in the gas apparatus of M. Mille, and the projection of the inflamed jet of the two gases on the magnesia of the lamp of M. Carlevaris, of Genoa. This lamp has been now greatly improved: for the lime cylinders of the Drummond light the learned Professor substitutes thin plates formed of magnesia and chloride of magnesium, which he places singly in small lamps, but grouped in a cylindrical form in lighthouses, &c., and which have the great advantage of being transparent, also of throwing intense light in the four directions. We tried one of these new lamps at a lecture given at the Agricultural Club in the Rue de Baune, and it produced wonderful effects; it is a complete revolution in the system of the Drummond light.

As we are on the subject of oxygen, justice compels us to remark an error which escaped our notice. We said a word, in our report of the Academy of Sciences, of the process of the distinguished chemist M. Mallet, founded on the property possessed, by the protochloride of copper Cu_2Cl, of absorbing the oxygen of the air and of being changed into the oxychloride $CuCl,CuO$, susceptible, when it is heated to a temperature of 400° C., of parting with this oxygen and returning to the state of protochloride, and so on. We understood from the remarks of M. Dumas, who presented the note of M. Mallet to the Academy, that, to remove the oxygen from the oxychloride, M. Mallet had recourse to steam, like M. Tessié de Mothay. This is not the case. The oxygen is driven off by the sole action of heat, which does not exceed that of the decomposition of chlorate of potash, and permits operations to be carried on, upon a small scale, in glass vessels. A kilogramme of protochloride alternately oxidised by a current of hot air and deoxidised by heat gives out 28 to 30 litres of oxygen gas without any appreciable loss of substance. We remark the difference, 46 litres, of oxygen gas furnished by a kilogramme of manganate, and 30 litres obtained by a kilogramme of protochloride. Also we remark especially the difference of the process of M. Archereau, which requires to be treated by enormous pressures for the mix ture of oxygen and sulphurous acid, and the processes either of M. Tessié de Mothay or M. Mallet, which do not require condensation or refrigeration, but yield only a simple mixture of steam and oxygen or of heated oxygen.

Before quitting this subject, let us announce that all those having recourse to the Drummond light are obliged to use, when they have no gasometers, india-rubber bags (at least on the Continent), which are expensive and treacherous; a simple pinhole renders them unserviceable. They can obtain the air-sacks invented by M. Galibert, of 111, Boulevart de Sébastopol, Paris, of whom we spoke in one of our last articles, and whose patent respirator for preserving life in noxious vapours is sold by the Patent Invention Company, No. 45, Little Britain, London. Constructed of two strong pieces of cloth, each having received on the inside layers of india-rubber varnish, which can be increased to any number, and strongly pressed together, these sacks of 13 to 33 gallons and more can serve perfectly for containing and transporting air, oxygen gas, &c., without any perceptible loss for some days. Neither have they the bad odour of india-rubber sacks, and consequently communicating none to the gas which escapes. The recipients which serve for the inhalation of oxygen gas or protoxide of nitrogen should henceforth be constructed of Galibert's impermeable cloth. India-rubber bags should be forthwith abandoned. Also it is well to remember that the experiments of Mr. Graham prove that india-rubber yields readily to the diffusion of gases. If, for example, we fill one with gas, the air enters and renders it more and more explosive.

We have the best possible news of the trials that are being made at Lille of the process of cold bleaching by permanganate of soda and hyposulphite of soda. The question at the present day seems to have been completely resolved. It may perhaps be recollected by our readers that the solution of hyposulphite of soda and the manganate should receive in addition a small quantity of hydrofluosilicic acid. This, consequently, had to be produced in large quantities, the more necessarily as it is imperatively requisite for the new processes of dull engraving on glass, for which a great future success is reserved.

Now we learn that M. Tessié de Mothay has succeeded in preparing, on as large a scale as is required in treating by heat in large furnaces, a mixture of fluate of lime, sand, and other substances adapted to render the reaction or the reduction more easy. When this acid is produced abundantly and economically, the great industry of soda will completely enter upon a new career. We purpose returning to this great discovery, of which we only now give a slight sketch.

Let us mention another success. M. Lantier, formerly a simple shoemaker, but whom an irresistible vocation drew into the science of electricity, and who has already

distinguished himself by the construction of a regulator and by the fabrication of artificial carbons for the electric light, is at present occupied in the solution of two great questions—1. To construct magneto-electric machines with a power two or even four times greater than those of the Alliance Company, or even the machines of Mr. Wilde, without the excessive velocity of the armatures of the latter, and without increasing the force necessary to put them in motion; 2. A burner of the electric light being given, to divide it into two, three, or four other burners without additional motive power, and by the simple addition of new regulators in communication with a common circuit. Aided by the support of one of my young brother labourers, M. Lantier has been able to construct the necessary apparatus, and they will figure at the Universal Exhibition. Let us not forget to say that, on his part, M. Van Malderen, the able director of the workshops of the Rue du Puits Artésien, Passy, to whom the magneto-electric machine of the Alliance Company owes its actual admirable qualities, is actively occupied in perfecting them, in spite of the challenge given by Messrs. Wilde, Wheatstone, Siemens, Lantier, &c.

The success of the *Mille* gas-lamp, with its double envelope and absorbing sponge, exceeds all expectations. They are sold by thousands.

The writer here wishes to remind the readers of the Chemical News, as well as all the *savants* and manufacturers in England, that he places himself entirely at their disposal to exhibit, defend, and make known their rights. Our lecture-hall at the Exhibition, our lectures, pen, influence, &c., will be available for them. In order not to sink under the pressure of so much toil, we have secured the services of learned and devoted co-operators, of which we shall soon publish a list. We are ready prepared to answer all appeals made to us. F. Moigno.

PROCEEDINGS OF SOCIETIES.

ROYAL INSTITUTION.

A Course of Six Lectures "*On Coal Gas*," by Dr. Frankland, F.R.S. (Lectures III. and IV.—March 14 and 16, 1867.)

Construction and Use of Photometers—Gas-burners—Conditions necessary for obtaining a Maximum Amount of Light in the Consumption of Gas—The Constituents of Crude Coal Gas—Impurities—Diluents—Illuminants.

The subject which was commenced in the last lecture—the measurement of the illuminating power of flames—was continued. The method of using a gas-meter during photometric experiments, for the measurement of the quantity of gas consumed, was shown, and the various kinds of jets from which gas might be burnt were examined. When gas was first introduced it was burnt from a single jet, and a flame from such a jet was made to burn on the lecture table. An experiment was then made, showing how the idea of the fishtail burner originated. Two flames burning from single jets, when brought in proper position, produced a fishtail flame, This was an important improvement in the method of burning gas; a table exhibiting the difference in the amount of light yielded by the same amount of gas when burning from single jets, and when burning from combined jets, showed that upwards of 50 per cent. more light was given by the latter. Dr. Frankland attributed the increase in light in gas burnt from a fishtail jet over the same amount burnt from a single jet, to the lessening of the velocity at which the hydrocarbons pass through the flame, caused by the striking in opposing directions of the two single flames. A number of argand lamps were exhibited: amongst them Leslie's, in which the burner consists of a circle of fine jets. Gas burnt in this lamp gives more light than when burnt in any of the ordinary forms of gas-lamps. It is therefore used by gas-manufacturers when testing the luminosity of the gas they supply; as, by burning the gas from it, they are enabled to record the light as equal to twelve candles (the standard fixed by Act of Parliament); the same gas, when burnt from ordinary jets, yielding a light equal only to ten candles. The conditions upon which obtaining the maximum amount of luminosity from a given amount of gas is dependent were described as the following:—1. Access of atmospheric air; 2. Velocity at which the hydrocarbons are driven through the flame; 3. Density of the atmosphere as measured by the barometer.

The lecturer then made an experiment to show the effect which an admixture of atmospheric air with coal gas had on the luminosity. Three flames were placed on the table: one burning cannel gas, another the same with 10 per cent. of air, and the third with 40 per cent. of air. The effect was striking, and showed that the admixture of air greatly decreases the illuminating power. It was mentioned that Professor Erdmann, of Leipsic, had made this property of admixed air a means of determining the illuminating power of coal gas, the value of the gas under examination being determined by the amount of air necessary to nullify its luminous effect. The lecturer explained that this action of air was due chiefly to the cooling effect it exercised in passing through the flame.

A little device for increasing the light given by a gas flame was here shown, invented by Mr. Scholl, and termed the "Platinum Perfecter." Some flames were tried with these perfecters, and the results were certainly astonishing. Dr. Frankland offered an explanation of their action. He believed that flames with them yielded more light than ordinary flames, in the same way that fishtail flames yielded more light than flames from single jets—that is, by the diminution of the velocity with which the hydrocarbon gases are driven through the flame. An experiment to show the effect of atmospheric pressure was made. A flame was burnt under a receiver, and as the air was gradually exhausted the flame gave less light. The converse experiment of condensing the air in the receiver showed that the flame under these circumstances became more luminous. The fact that atmospheric pressure influences the amount of light was thus made evident, and the decrease or increase in illuminating power was stated to be directly proportional to the atmospheric pressure. Other experiments relating to atmospheric pressure were the following:—1. A mixture of hydrogen and oxygen at the ordinary pressure was exploded in a closed eudiometer. Since these gases expand at the moment of ignition to about ten times their ordinary volume, they were under a pressure of about ten atmospheres. A brilliant flash resulted. 2. A similar mixture was exhausted to a pressure of only $\frac{1}{10}$th of an atmosphere, so that at the moment of ignition about the ordinary pressure of the atmosphere would be obtained. The light, when the current was passed, was very feeble, with the theatre darkened. 3. A mixture of hydrogen and common air was condensed so as to contain the same amount of oxygen as in the first experiment. The flash was about equal in brilliancy to that obtained in Experiment 1.

The effect of temperature upon the illuminating power of flames was again brought forward. An argand flame was burnt first in atmospheric air; afterwards it was partially fed with oxygen; the luminosity was considerably increased. The luminosity of ignited carbon at three different temperatures was compared—carbon ignited by a hydrogen flame; secondly, as in the preceding, with the addition of a stream of oxygen; and, thirdly, carbon points ignited by a voltaic current. In demonstration of the same fact, lime was heated in a hydrogen flame, and this was subsequently fed by a stream of oxygen.

The following methods of increasing the light of a coal-gas flame were given:—1. By feeding the flame with oxygen. 2. By decreasing the abstraction of heat from

the flame. 3. By heating the gases before they enter into combination. The increase in luminosity obtained by the last of these methods was illustrated by making both the coal-gas and air pass through a charcoal furnace before they came in contact. A lamp was shown in operation, where the same process was employed. It was constructed on the argand principle. Direct ingress of air below the flame was prevented by a glass plate, and by two glass cylinders a current of air passing in at the top of the outer one was maintained.

Air was burnt in an atmosphere of coal-gas, and attention was drawn to its slight luminosity. The experiment was afterwards made with two jets of air burning close to each other; a very good light was then obtained, and the following explanation was given:—In the combustion of coal-gas in air there are two radiating surfaces—the combustion of the hydrogen with the air, and that of the carbon. In the reverse experiment the flame possesses only one radiating surface, and thus the increase in light when two jets were made to burn close together. The subject of the constituents of coal-gas was then entered into. They were divided into impurities, diluents, and illuminants. Sulphuretted hydrogen, chloro-sulphur compounds, ammonia, carbonic acid, and bisulphide of carbon came in the first class; in the second, hydrogen, carbonic oxide, and marsh-gas; in the third, olefiant gas, butylene, vapours of hydrocarbons, propylene, and acetylene.

An experiment illustrative of the manner in which sulphuretted hydrogen is formed in the manufacture of coal-gas was then made. Hydrogen, being one of the products of the decomposition of coal by heat, was passed over sulphide of iron (which would represent the pyrites found in coal) heated in a bulb tube, and the presence of sulphuretted hydrogen shown by the reaction upon lead paper. Coal gas, it was stated, as supplied in London, was, however, always free from this impurity. This is not the case with bisulphide of carbon, which, on the contrary, is generally present. This impurity has the effect of lowering the igniting point of hydrogen. It was shown that a glass rod only very moderately heated inflamed such a mixture. There need be no fear, however, of this lowering of the point of ignition taking place in the presence of coal gas. The lecturer had found that a minute trace of this gas destroyed the lowering tendency; this, in fact, was shown. Coal gas in too minute quantity to exercise a visible effect on the luminosity of the flame made it require a much higher temperature than in the preceding experiment. The fourth lecture was closed with an experiment showing the bleaching properties of the product of combustion of bisulphide of carbon upon a red rose.

ROYAL SOCIETY.

March 14, 1867.

Lieut.-General SABINE, *President, in the Chair.*

THE following communications were read:—

"*On the Theory of the Maintenance of Electric Currents by Mechanical Work without the Use of Permanent Magnets,*" by J. CLERK MAXWELL, F.R.S. The author commenced his paper by saying that the machines lately brought before the Royal Society by Mr. Siemens and Professor Wheatstone consist essentially of a fixed and a movable electro-magnet, the coils of which are put in connexion by means of a commutator. The electro-magnets in the actual machines have cores of soft iron, which greatly increase the magnetic effects due to the coils; but, in order to simplify the expression of the theory as much as possible, he would begin by supposing the coils to have no cores, and, to fix our ideas, we might suppose them in the form of rings, the smaller revolving within the larger on a common diameter. The author concluded his paper, which was an elaborate mathematical one, with the following explanation:—Without the shunt, the current in the secondary coil is always in rigid connexion with that in the primary coil, except when the commutator is changing. With the shunt, the two currents are in some degree independent; and the secondary coil, whose electric inertia is small compared with that of the primary, can have its current reversed and varied without being clogged by the sluggish primary coil. On the other hand, the primary coil loses that part of the total current which passes through the shunt; but we know that an iron core, when highly magnetised, requires a great increase of current to increase its magnetism, whereas its magnetism can be maintained at a considerable value by a current much less powerful. In this way the diminution in resistance and self-induction due to the shunt may more than counterbalance the diminution of strength in the primary magnet. Also, since the self-induction of the shunt is very small, all instantaneous currents will run through it rather than through the electro-magnetic coils, and, therefore, it will receive more of the heating effect of variable currents than a comparison of the resistances alone would lead us to expect.

"*On a Magneto-electric Machine,*" by W. LADD. See page 141.

"*On Certain Points in the Theory of the Magneto-electric Machines of Wilde, Wheatstone, and Siemens,*" by C. F. VARLEY, Esq., in a letter to Professor Stokes, Sec. R. S.

Fleetwood House, Beckenham, S.E.,
February 23, 1867.

My dear Sir,—Professor Wheatstone showed that a shunt put into the circuit of the electro-magnet increased the power greatly, but the explanation that it increased the power by equalising the resistance of the armature and that of the electro-magnet is either wholly incorrect or very nearly so.

Yesterday I had an opportunity afforded me by Mr. C. Siemens of experimenting with his machine, in which the electro-magnets have each a resistance of about 250 Ohms = 500 Ohms, the armature 400 Ohms.

On adding a shunt to the electro-magnet, the flame was greatly increased.

The two electro-magnets when connected in series had a resistance of about 500 Ohms. I then connected them in a double circuit, the resistance in this case being about 125 Ohms. By this means the same result as regards resistance could be obtained as by a shunt, with the difference that the power expended in the shunt is lost in heat; while reducing the resistance by the double circuit caused the whole force to be expended on the electro-magnet.

The results of the experiment were—

1st. The shunt invariably increased in power.

2ndly. When the magnets were joined in double circuit, the power was greatly reduced.

The explanation is to me obvious. In a Ruhmkorff's coil, where the iron core is divided into fine wire, so that the dying magnetism cannot set up currents in the iron core to prolong its existence, the magnetism is very rapidly lost, and the make-and-break hammer works very rapidly, sometimes as fast as sixty beats per second.

If the secondary circuit be closed so that the currents can flow, the make-and-break hammer works very slowly, indeed one or two beats per second; and in 1856 I published a description of electro-magnets whose action was very slow, and which were rendered sluggish by a copper cylinder around them.

Wilde's armature, when revolving, sends intermittent currents around the electro-magnet, whose circuit is broken at every half revolution of the armature.

Were the magnets composed of fine iron wire, the magnetism would die away rapidly, producing a violent current by its efforts to maintain itself, as in the Ruhmkorff's coils. (This current is called by foreigners the extra current.)

The shunt which Wheatstone inserted carries this current across, and so maintains the magnetism of the electro-magnets until the armature gives a second impulse. The current in this shunt will be found to travel in alternate directions; not so that on the electro-magnet.

When the armature is discharging its current into the electro-magnets, the current in the shunt is in the direction it would have if the shunt were in circuit solely with the armature.

When the armature is changing poles and is disconnected, the secondary current is in full play, and the current in the shunt is in the direction of the current prolonged in the electro-magnet—that is, of the extra current.

The force expended in the shunt is wasted in heat; but a secondary wire on the electro-magnet or a copper cylinder would very greatly add to the power by maintaining the magnetism, and not consume uselessly the force now wasted in the shunt.

The overlapping of the armature and the solid mass of the electro-magnets tends to maintain imperfectly the magnetism during the intervals of no current from the armature; and but for this the machines, whether they be Wilde's, Wheatstone's, or Siemens', would none of them work.

In 1860 I published a description of two machines I had constructed, and in 1862, at the Universal Exhibition, I exhibited a machine for adding mechanical force to static electricity without friction. A machine similar in principle, but a little different in construction, has been exhibited recently under the name of Holtz.

One of my machines bears to the other precisely the same relation that Siemens' or Wheatstone's does to Wilde's.

If these be of sufficient interest to the Royal Society, I shall be happy to exhibit them. I am, &c.

C. F. Varley.

SOCIETY OF ARTS.

On the Synthesis and Production of Organic Substances and the Application which some of them receive in Manufactures, by Dr. F. Crace Calvert, *F.R.S., F.C.S., &c.*

Lecture II.

(*Continued from page* 110.)

Having thus studied the series of molecular and chemical actions, by which starch is transformed into sugar, dextrine, glucose, alcohol, acetic acid, mannite, lactic acid, and butyric acid, let us still pursue the interesting transformations of sugar into one or two more products. Thus, if starch or sugar is mixed with peroxide of manganese and sulphuric acid, and heat is applied, a most violent chemical reaction ensues, and the most important product thus generated through the oxidation of the sugar or starch by the oxygen of the oxide of manganese, liberated by its contact with sulphuric acid, is an acid referred to in my last lecture, namely formic acid, a substance found to characterise ants, the artificial production of which acid I described to you by methods which have been devised by M. Berthelot. Again, if we take starch or sugar, and act upon it with nitric acid or aquafortis, we shall convert it into a white crystalline substance, oxalic acid, which for many years was entirely extracted from a wild plant called *Oxalis acetosella*, which in fact was the only known source of obtaining a substance so extensively used by the cleaners of straw-bonnets, and in calico-print works, as well as by the careful housekeeper to remove iron-moulds from linen. At the present day, through the progress of chemistry, a pound of oxalic acid is not dearer than an ounce was formerly, for not only is oxalic acid obtained by the action of nitric acid on sugar, but it is also produced in large quantities at Warrington, in Lancashire, by Messrs. Roberts, Dale, and Co., through the action of a mixture of caustic soda and potash on sawdust, where, under the oxidising influence of the alkali incited by heat, the lignin, or fibre of the wood, which has an isomeric composition with that of starch, is oxidised and converted into oxalic acid. It would carry me far beyond the limits of a lecture were I to examine in detail how those substances in their turn can be converted into others, or the numerous classes of substances to which they give rise. I must, therefore, content myself with examining with you generally the subject under consideration, leaving details for the student. It will be easy to conceive what an amount of useful information the student will derive from such a pursuit; and you will see this more clearly if I lift up a corner of the veil, and give you an insight into those treasures of information. Let me, therefore, refer to some of the transformations of alcohol, a substance so well known to all of us by its presence in most of the beverages we take, and also from its extensive employment in arts and manufactures.

The conversion of alcohol into ether presents one of the most interesting and remarkable instances known in chemistry of the unfolding of a substance into two others, under the influence of certain molecular forces known to chemists (but yet badly explained) as actions of contact, or catalytic actions—that is to say, that science has observed several instances where a substance, when placed in the presence of another, under stated circumstances, will undergo special chemical decompositions, quite different from those which it will experience if the other substance is absent. The unfolding of alcohol into ether and water is a remarkable example of this class of molecular actions. Thus, if 70 parts of strong alcohol are carefully mixed with 100 parts of concentrated sulphuric acid or vitriol, and the whole allowed to remain for a few hours in contact, and are placed in a retort, to which heat is applied, so as to raise the temperature to 284°, it will be observed that one molecule of alcohol will split itself into one molecule of ether and one molecule of water. If such a transformation was to stop there, interesting as it is, it would be only similar to many others which I have brought before your notice. But such is not the case; for if in the heated fluid a small continuous stream of strong alcohol is introduced, it will be found that as the alcohol reaches the heated mass it will unfold itself into water and ether, which distil and still keep separate in the condensed part of the apparatus or receiver. Therefore, under the influence of a compound called sulphovinic acid, and heated at 284°, the alcohol which is introduced in such a mass is unfolded, as just stated, into two compounds which cannot unite, though they were united before they came in contact with the sulphovinic acid, or had experienced the catalytic action of the sulphovinic acid or sulphuric acid.

I hope you do not forget that in my last lecture I called your attention to another action of sulphuric acid on alcohol, viz., that if three parts of sulphuric acid were mixed with one of alcohol, and heat applied, the sulphuric acid, instead of separating one equivalent of water from the alcohol, so as to transform it into water and ether, would in that case remove two molecules of water, retain them, and liberate a gas which we called olefiant or ethylene. If, instead of acting upon alcohol with sulphuric acid, we act upon it with nitric acid or aquafortis, we produce nitric ether, or what is commonly called spirit of nitre; and if we mix alcohol with acetic acid, or, what is still better, with a mixture of acetate of soda and sulphuric acid, we obtain a most agreeable perfumed substance called acetic ether, which contributes largely to the flavour of wines and spirituous liquors. In fact, a great variety of compound ethers can be produced by bringing alcohol in contact with an acid, and applying heat; or, what is still more effectual, by bringing into play the action of still more powerful acids, such as sulphuric or hydrochloric, which by their presence help the transformation of alcohol into those compound

ethers so much used in medicine as therapeutic agents. Again, if to a mixture of alcohol and sulphuric acid a small quantity of manganese be added, and a gentle heat applied, a new substance is produced, differing entirely in its properties from that which results from the action of sulphuric acid and peroxide of manganese on sugar, for in that case formic acid is produced, whilst, in the one now under consideration, the substance called aldehyde is generated, which substance is characterised by the remarkable property it has of reducing the salts of silver, instances of which you have no doubt often remarked in the metallic globes in shop windows, which present a brilliant reflecting surface, due to a silver deposit, resulting, generally speaking, from the reduction of a salt of silver, by means of aldehyde. Lastly, this substance, which was two or three years ago a laboratory product, is now manufactured in large quantities, being used extensively for reducing, in conjunction with hyposulphite of soda, the splendid red tar colour known under the name of magenta, into that brilliant green which most of you have admired, under the name of *vert lumière*, from the fact that it maintains not only its green colour by artificial light, but that under the influence of that light its intensity is greatly increased.

NOTICES OF BOOKS.

Essai sur les Institutions Scientifiques de la Grande-Bretagne et de l'Irlande. Par Ed. Mailly, docteur en sciences, chevalier de l'ordre de Léopold, &c. Bruxelles: Hayez. 1867.

This work contains a succinct account of the scientific societies, the observatories, and the universities of the United Kingdom, with an outline of the Nautical Almanac and the British Museum. It professes to be composed from official sources, and, as far as it is possible to judge from a hasty survey, it is remarkably accurate. It would be difficult to find in our own language so brief and so clear a description, at the same time free from party bias. A few errors in proper names—for instance, "Sir Murchison"—mark the difficulty foreigners have in understanding our titles, but serve to set off the extreme accuracy of the descriptions of subjects so unintelligible even to many natives at our universities. If the book meets with the success it deserves, it will contribute greatly to that better understanding of English institutions and English character which is beginning to mark the foreign writers who attempt that hitherto incomprehensible subject.

CONTEMPORARY SCIENTIFIC PRESS.

[Under this heading it is intended to give the titles of all the chemical papers which are published in the principal scientific periodicals of the Continent. Articles which are merely reprints or abstracts of papers already noticed will be omitted. Abstracts of the more important papers here announced will appear in future numbers of the Chemical News.]

Bulletin de l'Académie des Sciences de Belgique. No. 12. December, 1866.

C. Glaser: "*Researches on some Derivatives of Cinnamic Acid*," First Part.

Monatsbericht der königlich-Preussischen Akademie. September-October, 1866.

Hincks "*On a Newly Discovered Record of Ancient Lunar Eclipses.*"

Kunst und Gewerbeblatt. November-December, 1866.

R. Wagner: "*Contributions to the Knowledge and to the Quantitative Estimation of the Tannic Acids.*"—C. F. Bazin, A.M., and C. F. Daude: "*A Method of Drying Gold-beaters' Skin in a Vacuum.*"—J. von Schwarz "*On the Manufacture of Refractory Articles from Clay Slate.*"—F. Jünnemann "*On the Transformation of Tallow into Adipocire.*"—"*On the Rusting of Weights.*"

Zeitschrift für Bauwesen. 1867. Nos. 1 and 2.

A. Cremer "*On the New Laboratory at Berlin.*"—Heidmann "*On Morin's Studies on Ventilation,*" continuation.—A. Meydenbauer "*On the Application of Photography to Architectural Plan Drawing and Surveying.*"—Boeckmann: "*Notes of a Visit to London, including Remarks on the Arrangement of Houses, Waterclosets, Lighting, Warming, Ventilating, Water Supply, Hotels, Kamptulicon, Covering for Roofs, Metropolitan Railway and Railway Stations;*" "*Notes of a Visit to London, including Remarks on the Street Traffic, Thames Embankment, Public Buildings, Crystal Palace, and the Royal Institute of British Architects,*" conclusion; "*On the Best Kind of Mortar for Use in Running Water.*"—Assmann "*On the Mint at Berlin.*"—Röder "*On obtaining Gold from the Old Silver Coinage of Prussia.*"—Louse "*On the Means of Preventing the Efflorescence of Saltpetre from Brickwork.*"—"*On the Water Taps of the New Laboratory of Greifswald.*"—Knoblauch "*On a New Gas Regulator.*"

Comptes Rendus. February 4.

Becquerel "*On an Electric Psychrometer and its Applications.*"—A. Mallet: "*A Method of preparing Oxygen.*"—L. Hermann: "*Note on the Danger of using Protoxide of Nitrogen as an Anæsthetic.*"—Bontemps: "*Remarks on a Memoir on Glass recently presented by J. Pelouze.*"—A. Béchamp "*On the Formation of Alcohol by the Living Organism which Produces the Pebrine.*"

February 11.—H. Deville and L. Troost "*On the Coefficient of Expansion, and on the Density of Hyponitric Acid Gas.*"—E. Fremy "*On the Isomeric Forms of Silicic Acid, and on Polyatomic Acids,*" First Memoir.—E. Frankland and B. F. Duppa: "*Synthetical Researches on Ethers.*"—A. Piche: "*Some new Remarks on the Invention of the Continuous Rotating Electrophorus.*"—Delenda "*On the present State of the Volcanic Phenomena at Santorin;*" "*On the Ancient Monuments discovered at Therasia.*"—C. M. Guillemin "*On the Discharge of the Battery and on the Influence of the Shape of the Conductors.*"—Colombi "*On a Method of Choosing Spectacles.*"—Van der Mensbrugghe "*On the Tension of Liquid Films.*"—C. Mene "*On the Quantity of Iron contained in some Ores from the Coal Districts of Central France, together with an Analysis of these Ores.*"—Reboul "*On some New Derivatives of Valerylene.*"—C. Saintpierre and A. Pujo; "*Researches on the Density of the Wines of the Department of the Hérault,* apropos *of the Question of Selling Wine by Weight instead of by Measure.*"—Felici: "*Description of a Lecture Experiment for rendering visible the Curve formed by a Vibrating Cord.*"

Revue Universelle des Mines. September-October, 1866.

A. Habets: "*Notes on the Mechanical Preparation of Ores: On P. Rittinger's and on Hundt's Continuous Apparatus.*"—"*On Blasting by Electricity.*"—"*On the Use of Nitroglycerine.*"—"*On Continuous Shaking Tables for Dressing Ores.*"—Gentele "*On the Treatment of Galena containing Zinc.*"—Dahne: "*A new Furnace for Extracting Zinc.*"—C. Zerrenner "*On the Deposits of Emery at Kornilowsk.*"—A. Von Groddek: "*Reply to M. Cornu's Note on the Numerical Relations which exist between the Chemical Equivalents of certain Minerals which occur in Veins.*"—Neimcke "*On the Use of Nitroglycerine in the Hartz;*" "*An Improved Blasting Powder.*"—Schuchardt "*On the Poisonous Properties of Nitroglycerine.*"—F. Abegg "*On the Application of Electricity to Blasting Purposes.*"—Schneider "*On Rittinger's Improved Shaking Table for Dressing Ores.*"—Rittinger "*On Hundt's Rotary Buddle.*"—Kleinschmidt "*On the Extraction of Copper, Silver, and Mercury at Stephanshütte, Hungary.*"—H. Honsell "*On the Extraction of Lead at Zsarnowitz, near*

Schemnitz."—Albert "*On the Extraction of Salt at Schönbeck.*"—Heberle "*On the Transmission of Motion by Wire Ropes and Hydraulic Pressure.*"—H. Tresca and C. Laboulaye: "*Researches on the Mechanical Theory of Heat.*"—A. Laussedat "*On the Theory and Use of Professor Robert Willis's Odontograph.*"—A. Payen: "*Note on Iodide of Potassium, and on the Acetates and Oxides of Lead;*" "*On Diastase and Woody Tissue.*"

NOTICES OF PATENTS.

1823. *Manufacture of Iron and Cast-iron.* J. N. Fournel, Nancy, France. Dated July 11, 186.

In this invention the fuel is heated separately, and the carbonic oxide produced is led by pipes to the furnace in which the ore is to be heated, where it is mixed with compressed air, and a flame is produced similar to that of the laboratory blowpipe, by means of which the deoxidation of the ore is effected.

1827. *Producing Illuminating Gas.* W. G. Walker and R. F. Smith, Kilmarnock. Dated July 12, 1866.

An invention for producing gas from peat by saturating it with shale oil or petroleum or other mineral hydrocarbon, and applying heat in the usual manner.

1846. *Preserving Timber from Decay.* A. Prince, Trafalgar Square, London. A communication. Dated July 13, 1866.

The patentee claims the application of crude petroleum, with or without mineral paints or pigments, for preserving timber from decay.

Communicated by Mr. Vaughan, F.C.S., Patent Agent, 54, Chancery Lane, W. C.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

47. W. Way, M.D., Eliot Place, Blackheath, Kent, "Improvements in preparing phosphatic minerals for use as manure." Partly a communication from C. Henwood, Sombrero, West Indies.—Petition recorded Jan. 7, 1867.

358. W. S. Losh, Wreay Syke, Cumberland, "A method of manufacturing a salt or salts of ammonia."—February 8, 1867.

378. E. Gorges, Neuilly, France, "Improvements in preserving meat, poultry, and game."—February 9, 1867.

492. W. Clark, Chancery Lane, "Improvements in the manufacture and ornamentation of anhydrous, rectified, and double-faced toilet soaps." A communication from P. B. Mongeot, M.D., Boulevart St. Martin, Paris.

494. C. Kessler, Frankfort-on-Maine, "Improvements in the manufacture of carbonate of soda and of potash."—February 22, 1867.

505. P. A. Muntz, Keresley, near Coventry, Warwickshire, "Improvements in the manufacture of certain metallic alloys."—February 23, 1867.

512. E. Chapron, Luxembourg, "Improvements in the treatment of peat."—February 25, 1867.

564. M. Woolrich, Well House, Handley, Cheshire, "Improvements in means and apparatus employed for the cure of the disease called 'foot-rot' in sheep."

568. W. Clark, Chancery Lane, "Improvements in the means and apparatus for producing oxygen, and in the application of the same for metallurgical and other purposes." A communication from H. A. Archereau, Boulevart St. Martin, Paris.—February 28, 1867.

Inventions protected for Six Months by the Deposit of Complete Specifications.

651. W. H. Towers, New York, U. S. A., "A new and useful process whereby leather, wholly or partially tanned, or animal tissue of any nature, is made hard, semi-elastic, and transparent, and rendered a fit material from which to manufacture combs, buttons, buckles, eye-glass frames, splints, knife handles, articles of jewelry, and other articles now produced from vulcanised india-rubber."—Petition recorded March 7, 1867.

684. H. A. Bonneville, Rue du Mont Thabor, Paris, "A new and improved means of preserving solutions of certain plants and matters in a concentrated state." A communication from C. d'Estains, Rue de Chaillot, Paris.—March 11, 1867.

Notices to Proceed.

2783. J. Blackman and E. Blackman, Knightsbridge, Middlesex, "Improvements in medicine for the cure of whooping and other coughs."—Petition recorded Oct. 27, 1866.

2825. J. H. Shorthouse and J. Ferguson, Birmingham, "An improved process for recovering and utilising certain waste metallic products."—October 31, 1866.

2847. J. Harris, Threadneedle Street, London, "Improvements in apparatus for the production, distillation, and refining of hydrocarbon and other oils from shale, cannel, coal, peat, lignite, or other bituminous minerals."

2850. R. J. Gay, Badshot Lee, Farnham, Surrey, "An improved composition for coating walls or other surfaces so as to render them impervious to the action of water or moisture."

2858. F. Claudet, Coleman Street, London, "Improvements in treating waste solutions obtained from burnt cupreous pyrites."—November 3, 1866.

2873. N. F. Taylor, Manby Street, Stratford, Essex, "Improvements in means for operating on air or aëriform fluids by hydrocarbons for purposes of illumination."—November 6, 1866.

CORRESPONDENCE.

Standard Thermometers.

To the Editor of the Chemical News.

Sir,—Your correspondent "G. L.," who directed me as to the way of acquiring information, deserves an answer. I have waited to see if any other gentleman would give one, but as this is not the case, I beg that you will kindly insert this. According to "G. L.," the satisfactory explanation of the phenomenon—that correctly graduated thermometers acquire afterwards an index error which may amount to 2°—is given in any good treatise on physics; but if "G. L." will consult his books again, he will find it clearly stated that no satisfactory explanation has yet been given, and this was exactly the reason why I sought the same from a careful manufacturer like Mr. Pastorelli, who, by exact observations, might have found it out in the course of his long experience.

According to "G. L.," rise of the mercurial column is owing to the boiling of the mercury in the glass, and the slow after-contraction of the same. But how does this explanation harmonise with the real facts? As "G. L." has made careful thermometric observations, he is cognisant that the boiling of the mercury in the tube causes the mercurial column, by inserting it afterwards in ice-water, to rise 2°; it is, therefore, clear that the boiling of the mercury in the tube would rather tend to correct the error instead of increasing the same. The boiling of the mercury can, therefore, not be the cause of this phenomenon. That "G. L." did not accept it as an established fact follows from the after explanation, where the same is attributed to the one-sided pressure of the air. As regards the insufficiency of this statement, I have to refer your correspondent again to books where the refutation of it is clearly given, as it is there stated that thermometers which contain air acquire the same error as those with a vacuum; and if "G. L." had consulted a practical manufacturer, he might have learned that the

one-sided pressure amounts only to about ·4° for about 15 lbs. on the square inch, and cannot, therefore, explain a difference that reaches 2°. Yet "G. L." may complain that he did not mean that the error was owing to the boiling of the mercury, but to the force which was done by it to the glass, particularly as he states (a known fact) that the indications of a thermometer became incorrect after it had been exposed to high temperatures, the difference of these errors depending upon the composition of the glass. The error that would arise from this cause is not stated, and has been probably over-estimated. I find that it does not exceed more than ·2° to ·3°, even if the mercury has been heated to nearly the boiling point, provided it has not actually boiled. (This error will depend upon the composition of the glass.) Errors which are caused in thermometers by subjecting them to higher temperatures amount only to about 10 per cent. of those of which we originally spoke. But if the one-sided atmospheric pressure amounts only to about ·4°, and the fall in consequence of heating a thermometer to nearly the boiling point to ·2° or ·3°, it follows that if they acted in the same direction even both could not jointly cause the index error. We must therefore seek the real reason elsewhere. In the course of the above statements we have come to a new thermometric phenomenon, which likewise wants explanation—viz., how is it that thermometers, heated until the mercury actually boils, acquire afterwards a rise in the freezing point of about 2°, whilst a fall occurs of about ·2° if they are heated up to nearly the boiling point?

I am, &c. A Subscriber.

P.S.—I might have added that the heating of a thermometer in boiling water causes likewise the same index error of about ·2° as that obtained by subjecting it to a much higher temperature. I may also state that I am very much indebted to Mr. Pastorelli, he having kindly given me the results of a series of carefully conducted thermometric experiments.

[If "A Subscriber" will favour us with some of the valuable information he has acquired from Mr. Pastorelli in explanation of the above phenomena, it will doubtless be highly appreciated.—Ed. C. N.]

Science Teachers.

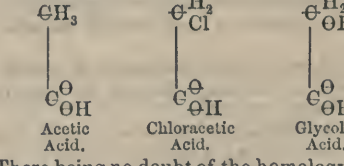
To the Editor of the Chemical News.

Sir,—I have only just seen the letter of a "Science Teacher" in the Chemical News of the 8th inst., or I should have noticed it earlier. Like him, I think that "my Lords" have made a wrong move in abolishing the special examinations for science teachers, if they only meant to replace them, as they have done, by the first and second class grade certificates of the May examinations. If "my Lords" consider that a certificate of a teacher's competency is necessary other than the success of the pupils he sends in for examination, it seems to me that to lower the standard of qualification as they have done is simply to render it almost, if not entirely, abortive. If an examination is necessary at all, let it be a good one; but I contend that the principle of restricting payment "for results" to teachers who possess the departmental certificate is a thoroughly unsound one, and quite opposed to those principles of free trade which are now universally recognised in all other matters. Why should A., who sends in three successful pupils to the May examination, and who possesses a certificate, be paid for their success, while B., who may send in six, receives no payment, simply because he has no certificate? What is the simplest and best test of the efficiency of teaching but the "results" themselves which come of it? A man may be able to pass a very fair examination, especially such an examination as certificated teachers have been hitherto called upon to pass, and yet make but a very poor teacher after all; whilst there are many men most competent to teach who, for one reason or another, may be unable or unwilling to subject themselves to the departmental examinations. For my own part I believe that the only just and sound principle is to leave the teachers to show their efficiency by the number of successful pupils which they can send in for examination, and to pay them accordingly. The new regulation certainly has the combined disadvantage of maintaining the old protectionist policy, whilst it at the same time abolishes the reason for doing so. I am, &c.

A Non-Certificated Teacher
(so far as the Department of Science and Art is concerned).

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Bibasic Acids (C = 12, O = 16).—A. Claus. According to the theory of types, oxalic and succinic acids belong to the same homologous series, whilst Kolbe derives oxalic acid from the diatomic radicle ($\overset{II}{C_2}O_2$) and succinic acid from the tetratomic radicle ($\overset{IV}{C_2}O_2$). Claus thought that the application to succinic acid of some of the methods of reduction which have been studied in connexion with oxalic acid would help to decide whether or no these two acids are homologous. He fruitlessly repeated experiments which some of Church's published researches led him to believe would be successful, and finding that neither zinc and succinic acid nor sodium amalgam and succinic acid gave anything but zinc and sodium salts of succinic acid, he entered the path opened by Frankland and Duppa, who have proved that one atom of oxygen in oxalic acid is replaceable by two atoms of an alcohol radicle. Succinic acid behaves under like conditions in a totally different manner from oxalic acid—indeed, ethyl will not replace oxygen in it. The results of his experiments with sebacic acid were perfectly analogous to those obtained with succinic acid. It would seem, then, that oxalic and succinic acids do not belong to the same series, and in further support of this view may be cited the impossibility of making the oxalic anhydride or chloride; nor can it be objected to this argument that the radicle of oxalic acid contains no hydrogen, for if the presence or absence of hydrogen in the radicle causes so great difference in the chemical behaviour of two compounds they cannot be correctly described as homologous. The error will probably be but small if we consider oxalic acid as a derivative of acetic acid, so far resembling glycolic and chloracetic acids, as may be seen on comparison of their formulæ:—



Acetic Acid. Chloracetic Acid. Glycolic Acid. Oxalic Acid.

There being no doubt of the homology of acetic and butyric acids, it follows that if oxalic and succinic acids are homologous, the latter acid should bear to butyric acid similar relations to those which have just been shown to exist between oxalic and acetic acids. A close examination, however, of the constitution of butyric acid shows that the acid resulting from its oxidation, though isomeric with, is yet different from, succinic acid; also the oxidation of butyric acid failed in Claus's hands to give succinic acid under the conditions described by Dessaignes. There are also strong theoretical reasons for doubting the identity with succinic acid of the acid obtained from cyanopropionic acid by Kolbe's and H. Müller's reactions. The chemical structure of succinic acid is best expressed by Kolbe's formula, modified, however, in accordance with the results

obtained by Simpson, who, in the synthesis of succinic acid from ethylenic cyanide, proves the existence in that acid of ethylidene, whilst Kolbe and Kekulé hold it to be ethylene.—(*Annal. Chem. Pharm.* cxli. 49.)

Ammonias, a New Class of Compound (C = 12, O = 16).—A. Wurtz. Pseudo-amylurea, under the influence of potash, splits into carbonic anhydride, ammonia, and iso-amylamine; this body, after distillation from caustic baryta, boils at 78·5° corr. (amylamine boils at 95°), and has sp. gr. 0·755 at 0° (amylamine 0·815); its aqueous solution precipitates metallic oxides and redissolves hydrated cupric oxide; if shaken with bromine, $C_5H_{12}BrN$ is formed; the chloride, platino- and aurochlorides were prepared, and are crystallisable. As in the pseudo-alcohol, so also in this base the individuality of the amylene molecule is preserved, as indicated by the formulæ—

$\underbrace{C_5H_{10},H(OH)}$ $\underbrace{C_5H_{10},H(NH_2)}$ $\underbrace{C_5H_{11}(OH)}$ $\underbrace{C_5H_{11}(NH_2)}$

Amylenic hydrate. Iso-amylamine. Amylalcohol. Amylamine.

(*Comptes R.* lxiii. 1121).

Furfuric Alcohol (C = 6, O = 8).—C. Stalmann. By the action of sodium amalgam on furfuric acid a viscid liquid is obtained of the composition represented by

$$\left.\begin{matrix}(C_8H_3O_2)\\H_2\end{matrix}\right\}C_2O,HO,$$

which appears to be identical with the alcohol obtained by Schmelz and Beilstein from furfurol.—(*Zeitsch. Chem.*, N.F., iii. 47.)

Glycolamidic Acids, the Constitution of.—H. Kolbe. Monoglycolamidic acid is constituted similarly to monochloracetic acid, from which it is derived by the replacement of the chlorine atom by amidogen, glycolic acid being acetic acid, in the methyl radicle of which H_1 is replaced by one molecule of hydroxyl (HO_2), as shown by the formulæ—

$\underbrace{(C_2H_3)[C_2O_2]O,HO.}$ $\underbrace{C_2\left\{\begin{matrix}H_2\\Cl\end{matrix}\right\}[C_2O_2]O,HO.}$

Acetic acid. Monochloracetic acid.

$\underbrace{C_2\left\{\begin{matrix}H_2\\HO_2\end{matrix}\right\}[C_2O_2]O,HO.}$ $\underbrace{C_2\left\{\begin{matrix}H_2\\H_2N\end{matrix}\right\}[C_2O_2]O,HO.}$

Glycolic acid. Monoglycolamidic acid.

Diglycolic acid results from the union of a molecule of glycolic acid with one of monochloracetic acid, with elimination of chlorhydric acid; it is no other than malonic acid in the methylene radicle, of which H_1 is replaced by one molecule of methoxyl; diglycolic acid being then in all probability oxymethylmalonic acid, diglycolamidic acid becomes methylamidomalonic acid, and its derivation from monoglycolamidic and monochloracetic acids is exactly analogous to the derivation of diglycolic acid just described. If this view be correct, the careful heating of diglycolamidic acid with soda-lime should give methylamidacetic acid (sarkosine) or a product of its decomposition. Similarly, triglycolamidic acid would spring from the union of diglycolamidic and monochloracetic acids, chlorhydric acid being eliminated; it is a tricarbic acid (tricarbonsäure), the trivalent radicle of which is a derivative of formyl, H_1 being replaced by dimethylamide.—(*Zeitsch. Chem.*, N.F., iii. 47.)

Synthesis of Oxalic Acid (C = 6, O = 8).—Berthelot has oxidised various hydrocarbons by means of potassic permanganate with the following results:—Acetylene gives oxalic and formic acids and carbonic anhydride. Ethylene gives the same. Allylene (homologous with acetylene) gives malonic and acetic acids and carbonic anhydride. Propylene gives malonic, oxalic, acetic, and formic acids and carbonic anhydride. Amylene gives the volatile and many of the fixed acids. Among the latter are probably pyrotartaric (the normal product), succinic, and malonic acids. Styrolene gives benzoic acid and carbonic anhydride, but phtalic acid could not be produced. He considers that the dibasic acids are the primary products, the monobasic acids being secondary effects. Thus allylene gives malonic acid as a normal product—

$$C_6H_4 + O_8 = C_6H_4O_8;$$

nascent malonic acid splits thus—

$$C_6H_4O_8 = C_4H_4O_4 + C_2O_4;$$

nascent acetic acid so formed is oxidised—

$$C_4H_4O_4 + O_6 = C_4H_2O_8 + H_2O_2;$$

and oxalic acid finally gives

$$C_4H_2O_8 = C_2H_2O_4 + C_2O_4. \quad (Comptes\ R.\ lxiv.\ 35.)$$

Nitrogen, Determination of.—Ch. Mène, by a modification of the ordinary method of analysis, is able to operate on 10—15 grammes of substance in each determination, and not only in commercial analyses, but also when working with pure substances. He employs earthenware retorts, such as are used for making oxygen from manganic binoxide, fills them with stick potash, and puts in the substance to be analysed in the form of little balls moistened with strong caustic soda solution, adapts a glass tube to the beak of the retort, heats the retort even to a cherry-red heat, and collects the ammonia disengaged in a chlorhydric acid solution. The ammonia, being generally accompanied by empyreumatic bodies, the colour of which prevents the use of a standard alkaline solution, must be weighed as chloroplatinate.—(*Comptes R.* lxiv. 42.)

Physostigmine (C = 6, O = 8).—O. Hesse has resumed the examination of the poisonous principle contained in the Calabar bean. The freshly prepared alcoholic extract of the bean is shaken with sodic bicarbonate and ether. Very dilute sulphuric acid takes the physostigmine from the ether, and in its turn gives it up when treated with sodic bicarbonate and ether; the ether, on evaporation, leaves the pure alkaloid. It is tasteless, uncrystallisable, capable of enduring for a short time a temperature of 100°, but presently decomposing, easily soluble in alcohol, ether, benzol, chloroform, and carbonic bisulphide, difficultly so in water. Its solution is strongly alkaline, and perfectly neutralises acids. Solutions of its sulphate, chloride, or acetate are tasteless and colourless, become pink on exposure to air, and are decolorised by reducing agents or animal charcoal. The coloration, which is intense when the solutions are made alkaline and heated, results from oxidation. Its formula is $C_{30}H_{21}N_3O_4$. A solution of iodine in potassic iodide produces with it a crimson precipitate; it is also precipitated by HgI, KI, HgCl, $AuCl_3$, and tannic acid, but not by platinic chloride.—(*Annal. Chem. Pharm.* cxli. 82.)

MISCELLANEOUS.

Elimination and Estimation of Nitric Acid contained in Well Water.—Having satisfied one's self of the existence of nitrates by preliminary experiments with the pyrogallic acid test given by me in No. 183 of the Chemical News, p. 257, evaporate half a gallon of the water down to about 6 or 8 ounces, and filter. Boil the filtrate with excess of sulphate of silver so as to abstract the chlorine, filter and precipitate the excess of silver by liquor potassæ, neutralise the filtrate with *q.s.* of dilute sulphuric acid, and evaporate it to dryness, so as to obtain nitrate and sulphate of potash; mix this residue intimately in a mortar with two or three times its bulk of powdered pipeclay or kaolin, place it in a small stoppered porcelain retort connected with a receiver containing distilled water and crystals of hydrate of baryta or strontia. On the application of a strong red heat to the retort, the whole of the nitrous acid will be driven over into the receiver. Absorption having taken place, filter the liquid, and evaporate carefully to dryness, redissolve the residue in distilled water, filter and again evaporate to dryness. Lastly, dissolve out the nitrate of baryta with distilled water, filter and estimate the amount of nitric acid by

titration with a standard solution of sulphate of ammonia (6 grains per drachm), taking into account the difference in the equivalents of sulphuric and nitric acid, every 60 minims representing 4·32 grains of nitric acid.—*John Horsley, F.C.S.*

London Well Water.—Dr. Letheby has lately again (for the fourth time) drawn the attention of the Sanitary Committee of the Commissioners of Sewers of the City of London to the dangers attending the use of the water of the City pumps. He shows conclusively—as Mr. Simon did seventeen years ago—that the coolness of such water is derived from substances, such as nitrate of potash and common salt, which are formed as the results of animal decompositions from churchyards and infiltrated soil. Surely, he argues—as was argued seventeen years ago—if you get these ultimate products, you must obtain with them some of the mediate ones; the latter specially dangerous in times of epidemics. The arguments of 1850 are repeated, and the latest analyses of these waters are very similar to those made then; but the more melancholy fact is, that the evils attendant upon their former use are more than ever demonstrated by the last epidemic. Such a demonstration was not needed, and while thanking the authorities for the light that they have thrown upon the spread of epidemics by surface water, we would suggest that the evidence is complete, and that no further experiments are at all necessary. At all events, we can assure them that another lapse of seventeen years, and scientific reports and analyses yearly upon the state of the London surface water for the further consideration of the matter, are simply so much time, trouble, and money thrown away.

On the Separation of Strychnine Salts by Carbolic Acid.—When a weak solution of hydrochlorate of strychnine is shaken with some drops of carbolic acid, the liquid assumes the appearance of an emulsion. It has then little activity when administered by the hypodermic method, but this relative innocuousness is due to a simple sluggishness of absorption, and not to a destruction of the strychnine by carbolic acid, for on removing this with ether, a limpid solution is obtained as energetic as at first. If the emulsion is carefully filtered and the filtrate treated with ether, it has no longer any toxic property; on the contrary, that which remains on the filter, being diffused in water and freed by means of ether from the carbolic acid which it contains, forms again the strychnine salt at first taken. Carbolic acid has the effect, therefore, of holding in suspension the strychnine salt, and singularly facilitating its separation. The author has found that strychnine can be easily separated in this way from putrescent animal matter. —*M. Paul Bert*, in the *Gazette Médicale.*

To distinguish Arseniuretted Hydrogen from Antimoniuretted Hydrogen.—On passing a mixture of these two gases through a tube containing solid pieces of caustic potash, these become covered with a brilliant metallic coating of antimony, whilst the arseniuretted compound escapes undecomposed. A ley of potash, density 1250, only acts very slightly in a similar case. The fragments of potash which have become metallised by the deposit of antimony are altered in the air; they soon become white in water, the metallic coating falling to the bottom; but when they are attempted to be collected on a filter they dissolve before the liquid has even passed through. In the clear filtrate, antimony is found in solution, and the author fancies that it exists in the form of antimoniate.—*M. Dragendorff*, in *Zeitschr. analyt. Chem.* 1866, p. 201.

Employment of Hypochlorite of Magnesia in Bleaching.—The following has been discovered in an examination of the action of hypochlorite of magnesia, and the preference which is given for it when delicate tissues have to be bleached:—1. This hypochlorite decomposes more easily than the lime compound; 2. The liberated magnesia is without action on the tissue. This cannot be said of lime. The best way of preparing hypochlorite of magnesia consists in decomposing sulphate of magnesia with hypochlorite of lime. When the sulphate of magnesia contains manganese, the liquid assumes a red colour, and loses its bleaching power.—*MM. Bolley and Jokisch*, in *Schweiz. Polyt. Zeitschr.* 1866, p. 120.

ANSWERS TO CORRESPONDENTS.

*** All *Editorial Communications* are to be addressed to the Editor, and *Advertisements* and *Business Communications* to the Publisher, at the Office, 1, Wine Office Court, Fleet Street, London, E.C. *Private* letters for the Editor must be so marked.

L. O. Q.—A patent for the introduction of sulphur into soap was taken out in 1862, but was not proceeded with.

J. Johnstone.—Marble may be rendered black and capable of taking a high polish by immersion in boiling pitch. Many other stones and minerals may be blackened, uniformly, superficially, or in fissures, by the same means.

A.—Taylor and Francis, Red Lion Court.

Student.—Send the amount to our publisher, and the book will be sent by post.

M. M. N. N.—Fractional distillation is a most imperfect and unsatisfactory way of separating members of the same series. It is only resorted to when other means fail, or as a preparatory stage to the final adoption of a chemical process of purification.

M. R. S.—By naphthalising the gas you may be able to increase its illuminating power sufficiently to take a faint photograph by it, but the results, at best, are very unsatisfactory. Why not use magnesium wire?

Vitriol.—Gay-Lussac's process for absorbing the nitrous acid, which escapes from the vitriol chambers in a tower containing coke saturated with oil of vitriol, is the one most commonly used.

John C.—The best inorganic green pigment is a preparation of oxide of chromium. A sample was exhibited in 1862 under the name of Veronese green; it was a magnificently brilliant blue green, unaffected by air, sulphuretted hydrogen, light, or time. The exact method of preparing it is not known.

Inquirer asks where he can find information on the products obtained by passing coal gas through sulphuric acid, and on the action of nitric acid upon those products. He has looked at the article on coal gas in Watts's "Dictionary of Chemistry," but cannot find that the action is alluded to, except that of dilute sulphuric acid and sawdust, as in the Rev. Mr. Bowditch's test.

Enduit Ruolz.—A correspondent wishes for information respecting the cement spoken of in the following extract from "A Canoe Voyage," by P. G. Hamilton, in the February number of the *Fortnightly Review*, p. 179:—"The most suitable material, because the easiest to manage, seemed to be paper, but the difficulty was to find a glue which would paste the paper together and yet resist water. This seemed at last to offer itself in a kind of mastic invented by the celebrated chemist Ruolz, and known as the *enduit Ruolz*. A light skeleton of laths was made for me by an ordinary joiner, and I covered this with several thicknesses of stout waterproof paper, taking care to give plenty of *enduit* between the layers. The canoe so built had a paper deck, and when finished looked exceedingly neat, presenting the appearance of an iron vessel. As to strength, the best proof of it is that, although the canoe has met with a thousand obstacles, no rock or snag has ever penetrated its paper covering; whilst the deck, though I always walked upon it to get in and out, is just as fresh as the day she was launched. It happened, however, that I put my boat to hard work at least six months too soon. The *enduit Ruolz*, though in time it becomes as hard as marble, and will even take a polish and look like polished black marble, hardens very slowly indeed when shut up between layers of waterproof paper."

Books Received.—"Familiar Lectures on Scientific Subjects," by Sir John Herschel, Bart., K.H., M.A., &c.; "An Essay on Dew," by W. C. Wells, edited by L. P. Casella, F.R.A.S.; "Chemistry, Inorganic and Organic," by Charles L. Bloxam; "The Sewage of Towns," edited by John Hitchman, M.R.C.S.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On the Metropolitan Water Supply during the Year 1866, *by* E. Frankland, *F.R.S.**

The following tables contain a summary of the results of my analyses of the metropolitan waters, executed for the Registrar-General, during the year 1866.

Table A. records the amount of solid impurity left on evaporation and desiccation at 120°—130° C. (248°—266° F.) of 100,000 parts by weight of water. Table B. the loss which this solid matter suffered on incineration. Table C. the amount of oxygen required to oxidise the organic matter contained in 100,000 parts of the water; and Table D. the degrees of hardness or parts of carbonate of lime (or its equivalent of other hardening salts) contained in the same weight of water. Thus, in January, 1866, we find, on referring to Table A., that 100,000 lbs. of the water delivered to consumers by the Chelsea Company contained 30·12 lbs. of solid impurity, of which, as shown by Table B., 1·44 lb. was driven off by incineration. From Table C. we learn that ·1184 lb. of oxygen was required to oxidise the organic matter in 100,000 lbs. of the said Chelsea water; whilst from Table D. we find that 21·4 lbs. out of the 30·12 lbs. of total solid impurity consisted of carbonate of lime or other soap-destroying material, which communicates to all the water delivered in London its excessive hardness.

Table E. exhibits a comparison between the years 1865 and 1866 as regards the composition and properties of the waters supplied to the metropolis. From this table it will be seen that, with two exceptions—the New River and South Essex—all the waters were harder and contained more solid impurity in 1866 than in 1865. The water delivered by the New River Company was softer and contained less solid impurity, whilst the South Essex Company's water contained less solid impurity, but was harder, in 1866 than in 1865. With one exception, the organic and other volatile matter was in every case markedly less in 1866 than in 1865. The exception is the water of the New River Company, which exhibits a very slight excess of this matter in 1866 as compared with the previous year. The amount of oxygen required to oxidise the organic matter contained in the waters was also less in 1866 than in 1865, with two exceptions—viz., in the New River and South Essex Company's waters. It must be remarked, however, that in this respect the Kent, South Essex, and New River Company's waters are greatly superior to those of all the other companies in both years.

On a New Mineral from Borneo, by Professor F. Wöhler.

This mineral is found mixed with the native platinum brought from Borneo. It forms small grains or globules of a dark black-grey colour, and of considerable lustre. Many of these grains show brilliant crystalline facets, which are the faces of regular octahedra. The new mineral is very hard and brittle. Its powder is dark grey. Its density exceeds 6, according to an approximate determination. When heated it decrepitates like galena; it does not fuse before the blowpipe, but diffuses a strong odour of sulphurous acid, and then of osmic acid. It is not attacked by aqua-regia, nor by bisulphate of potash. Fused in a silver crucible with hydrate of potash and nitre, it dissolves to a green mass. After cooling the mass is brown, and it dissolves in water with a magnificent orange colour. The solution has the odour of osmic acid, and nitric acid produces in it a black precipitate. From this it may be concluded that the new mineral contains as its principal elements osmium and ruthenium. It also contains sulphur. To estimate the latter, I heated the mineral to redness in a current of hydrogen until no more sulphuretted hydrogen was disengaged. The residue was exhausted many times by aqua-regia; there remained metallic ruthenium. A portion of this metal was estimated in the orange solution. This was evaporated, then neutralised by ammonia and brought to dryness, and the residue calcined in a covered crucible in an atmosphere of carbonate of ammonia. There remained metallic ruthenium. The osmium which volatilised was determined by difference. From this analysis the new mineral contains

Sulphur	31·79
Ruthenium	65·18
Osmium	3·03
	100·00

These numbers appear to show that the mineral is sulphide of ruthenium Ru_2S_3, twelve molecules of which are associated with one molecule of sulphide of osmium OsS_4.

PHYSICAL SCIENCE.

*Mr. Rodwell's Hydraulic Experiments.**

In the former of these papers (an abstract of which was given in the tenth volume of this journal, p. 175), Mr. Rodwell discussed the various modes by which air is carried down by a stream of water, more particularly for the purpose of explaining the action of the Catalan wa terbellows or trompe. The present paper treats of a different branch of hydraulics, and is divided into three parts, of the contents of which we give an abstract below. On account of the length of the paper, it will be impossible for us to do more than describe the general

* "On some Effects produced by a Fluid in Motion," No. iii., *Philosophical Magazine* for February, 1867.

heads of the research, leaving those who are specially interested in the subject to refer to the original.

In the first section the author treats of the "Effects produced by a stream of liquid (α) entering, and (β) issuing from a fluid mass at right angles to its surface." Under this head we have an account of the production of various surface currents, chiefly due to the so-called "lateral action"† of Venturi, which results from the negative pressure of a fluid in motion, for it has been well ascertained, and also demonstrated by Poisson on theoretical grounds, that the pressure exerted by a fluid in motion is less than its pressure when at rest. An explanation of the action of the water elevator, known as the "hydraulic belt," concludes this section.

In the second section we have an account of a number of experiments made to determine the "Amount of lateral action exercised by (α) a jet of water, and (β) a jet of steam of known pressure." The intensity of the action was determined by causing the jet to remove water from a graduated tube by impinging upon the orifice of the shorter limb of a siphon, the longer limb being immersed in the tube, so that the lateral action was exercised against a constantly increasing pressure of water in the longer limb of the siphon, until that pressure balanced the negative pressure of the moving liquid. The lateral action of a jet of high-pressure steam was measured in millimetres of mercury, representing the diminution of atmospheric pressure. Among other results it was found that the lateral action of a jet of steam having a pressure equal to 1165 millimetres of mercury (or 23 lbs. on the square inch) is competent to reduce the atmospheric pressure to one half. For lecture illustrations of lateral action, it is usual to employ air or steam in motion, but the author shows that it may be as readily demonstrated by the use of a fluid in motion, either by means of two appliances which would scarcely be understood without a reference to the figures, or by allowing a liquid "to flow near a sphere of oil floating in static equilibrium in a medium of its own density, when the sphere will be observed to lengthen itself into an ellipsoid, with its major axis at right angles to the direction of the influent jet."

In the third section the author describes some experiments illustrating the constitution of a descending liquid jet below the *vena contracta*. Savart, Plateau, Magnus, and others have proved that the opaque portion of a jet consists of detached masses of liquid, in alternating forms of (α) an ellipsoid with its major axis parallel to the axis of the jet, (β) a sphere, (γ) an ellipsoid with its major axis at right angles to the axis of the jet, (δ) a sphere, and so on. But these effects can only be observed by means of a revolving mirror, or some other contrivance for causing a body in rapid motion to appear motionless, and are therefore unsuited for the lecture table. Mr. Rodwell's object was to modify the experiment so that the above effects could be shown as a lecture experiment. "The mode of effecting this," he writes, "is to cause the cohesion acting upon the particles of a fluid mass floating in a medium of nearly its own density, to slightly preponderate over the gravitating force of the mass, and then, by slowly reducing the density of the medium, to allow gravity to act upon one portion of the mass." The author then describes two methods of showing the experiment, the second of which we give *verbatim*:—

"Prepare, as before, a mixture of alcohol and water" (possessing the same density as the oil employed); "introduce a quantity of oil sufficient to form a sphere from 40 to 50 millimetres in diameter, and let the density of the mixture be such that the sphere floats 20 or 30 millimetres below the surface, the entire depth of the liquid being from 175 to 200 millimetres. On heating the mixture, the sphere extends itself into an ellipsoid with its major axis at right angles to the liquid surface; it then gradually contracts at a point midway between the ends, until, as in the previous experiment, only a fine thread separates the two larger masses of oil; rupture then ensues, and the thread gathers itself into a sphere. The lower mass commences its descent as an ellipsoid having its major axis at right angles to the liquid surface, next becoming a sphere, then an ellipsoid with its major axis parallel to the liquid surface, once more a sphere, and so on, until it reaches the bottom of the vessel, while the upper mass of oil ascends to the surface, and comes to rest as a hemisphere with its plane surface in contact with the surface of the liquid."

The remainder of the paper is devoted to a consideration of the *rationale* of this experiment.

† "Recherches expérimentales sur le Principe de la Communication latérale du Mouvement dans les Fluides."

FOREIGN SCIENCE.

(From our own Correspondent.)

Paris, March 27, 1867.

The general section of the following learned societies of France is annually held during Easter week under the patronage of the Minister of Public Instruction, from April 23 to Saturday, the 27th.

The Council of the Scientific Association of France has decided that the general annual meeting for 1867 is to take place at Paris in the same week. In the day meetings will be held, according to custom, by the delegates of learned societies, in which papers only will be read. The Scientific Association reserve for themselves the progress made recently during the last years in different branches of science. M. Haton de la Goupilière is to describe the progress of mechanics; M. Bertin will treat on electricity; M. Lissajoux on acoustics; M. Cazin on heat; M. Troost on chemistry; M. Payen on the fertility of the soil and the means of preserving it; M. Hebert on the general movements of the crust of the earth and their causes; M. Milne Edwards on natural history. This will be a good opportunity for the different juries of the Exhibition of 1867 to meet together, and hold a meeting similar to those of the British Association for the Advancement of Science.

This Scientific Association, following up its own course—to encourage in France works relative to the improvement of the sciences—granted sums of money to M. Cazin, in order to enable him to continue his works relative to the mechanical theory of heat; to M. Bertin, for his studies on the constitution of ice; to M. Bourget, for acoustic apparatus; to M. Crova, for his improvements on Weber's galvanometer; to M. Baudin, for the construction of apparatus for comparing thermometers; M. Terquem, for his acoustic apparatus; M. Favre, of Marseilles, for enabling him to continue his works on physics and chemistry. The Council voted, moreover, a sum of 80*l.* to a gentleman, whose name we did not catch, towards his travelling expenses on his voyage through the interior of Africa; 20*l.* for the purchase of a barometer according to Fortin's method of construction, maximum and minimum registering, and a rain-gauge, which are to be entrusted to the English missionaries for meteorological observations.

We give some details of the photographometer or surveying table applied by M. A. Chevalier and well constructed by M. Duboscq. This instrument, admirably adapted to the use of photography for surveying purposes, operates automatically. Once set up, it takes off mechani-

cally the principal points of the horizon on a plate in a regularly determined time. This object-glass, similar in all respects to that of an 'ordinary' camera obscura, is mounted *vertically* on a circular table or plate, which turns round by clockwork, and can be accelerated or retarded at pleasure. The images of the salient points of the horizon formed by the luminous pencils of rays, which the object-glass renders convergent, cast at an angle of 90°, are made convergent on the horizontal plane by a total reflecting prism, and are thrown upon a perfectly centred sensitised collodionised plate. The whole of the sensitive surface is covered by an opaque screen or shutter, which works round along with the board, and which is provided with a very narrow slit in the middle line situated in the vertical plane passing by the optical axis and that of rotation. Under these conditions, when the complete revolution of the instrument has taken place, the sensitised plate marks exactly the angles made by horizontal lines drawn from the centre of the board or of the station to all points of the horizon which have passed by the optical chamber of the instrument. We can thus, instead of operating continuously, only take off any desired points of the horizon by the method of fixed sections. This contrivance is so adapted that the screen can turn while the object-glass remains fixed, so that the same object can be represented several times in different states of change.

M. Viollet le Duc, the celebrated architect, has had a plan made of the celebrated castle of Pierrefonds, now being restored, in a few days—an operation which would have taken several months by the usual methods.

M. Grenet has discovered the very remarkable fact of the decomposition of a certain number of bodies by the simple passage of a current of inert gas. For example, taking a solution of carbonate of lime, barytes, or potash through which passes a current of nitrogen, hydrogen, or air, the lime, barytes, or potash is precipitated, while the carbonic acid is set free. Under the same conditions, the sulphhydrates of the alkaline sulphides disengage sulphuretted hydrogen; the sulphites and the acetates lose the sulphurous and the acetic acids; the nitrates disengage oxides of nitrogen at temperatures much inferior to those which are generally regarded as the temperatures of decomposition. These phenomena are thus explained:—Taking, for example, the bicarbonate of potash: at ordinary temperature the tendency to dissociation is very weak, and in a limited atmosphere it only emits a feeble quantity of carbonic acid; but if we renew the atmosphere in contact with the carbonate, a fresh quantity of carbonic acid is produced, and the dissociation or decomposition of the salt gradually increases.

M. le Guin, from his latest experiments made with steel from the Imphy Works (Nièvre), on the improvement of the quality of steel in general, and at times by the addition of wolfram or tungsten, has arrived at the following conclusions:—The Bessemer apparatus can be used to combine tungsten with the steel; the loss of tungsten recognised by analysis does not exceed that observed in the processes of combination previously tried; ordinary grey (coke) iron, containing no steel, becomes, by being treated with wolfram, susceptible of being transformed into good steel, the decarburetted metal being in the converters; this opens a great field for the means of obtaining, with cast-iron, a steel of any quality desired; by this means it will be possible to obtain large castings of tungsten steel by the Bessemer process.

The clocks, watches, and chronometers of M. Menon, Rue de l'Eglise No. 10, Neuilly, leave nothing to be desired in the regularity of the marking of time. This is obtained by the compensation of the length of a lever, which acts upon the pendulum by means of rackwork. A metallic rod or wire, curved spirally and vertically *flat*, is fixed to the pendulum; one end is fixed to it, the other is connected with a small lever, the extremity of which is terminated by a small segment of a toothed wheel, which plays upon a rack fixed to the pendulum. When the temperature increases the coil expands, and the rackwork raises the pendulum-rod, and thus keeps the centre of oscillation at a constant point. The reverse effect is obtained when the temperature descends; the coil contracts, and the centre of oscillation is lowered. It is essential that the spiral coil should have exactly the same length and dimensions as the pendulum-rod.

F. Moigno.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, March 21.

Professor W. A. Miller, M.D., V.P.R.S., *President, in the Chair.*

The minutes of the previous meeting were read and confirmed, and the donations to the library announced. Major R. C. Stewart, Mr. J. H. Freeman, and Mr. R. H. Davey were formally admitted Fellows of the Society, and the following gentlemen were balloted for and duly elected—viz., Angus Fraser, M.A. and M.D., Aberdeen; Frederick S. Barff, M.A. Cantab., 16, North Audley Street, Grosvenor Square; and Mr. Alfred Tribe, Great Portland Street, London. The names of candidates read for the first time were—William Phipson Beale, Barrister-at-law, Stone Buildings, Lincoln's Inn, and Alfred Coleman, Plough Court, Lombard Street. For the second time were read the names of David Skinner Kemp, Bombay, and John Mackay, 119, George Street, Edinburgh.

Dr. J. H. Gladstone offered a few remarks "*On Phosphonitril.*" The body in question, PNO, was produced by heating the product of the action of ammonia gas upon the oxychloride of phosphorus. Its formation was thus explained:—

I. $PCl_2O + 2NH_3 = PNH_2Cl_2O + NH_4Cl$.
II. $PNH_2Cl_2O = PNO + 2HCl$.

The author had ascertained the loss by heat in the second equation, and found it to be 32·45 per cent., which was close upon the number demanded by theory—viz., 32·36. It is a white, solid, and very stable compound, fusible to a vitreous mass at high temperatures; not attacked by the ordinary acids or alkalies, but decomposed only by concentrated sulphuric acid. An analysis was made of it by fusion with carbonate of sodium and nitre, and this gave 50·73 per cent. of phosphorus instead of 50·82. Dr. Gladstone humorously said this was a compound that had more names than investigators, and he was now desirous of canvassing the Society as to the propriety of adopting for it the name of "phosphonitril." It had previously been called "phosphamide" and "biphosphamide," but it did not contain any hydrogen. The speaker then showed its mode of formation from the metaphosphate of ammonia by loss of two atoms of water, thus—

$$P(NH_4)O_3 - H_2O = PNO.$$

Mr. T. Sterry Hunt said that fifteen years ago he inserted a notice in *Silliman's Journal* referring to the constitution of this body, and described it under the old formula PNO_2. He then viewed it as the nitril of phosphoric acid, and compared it with NO, the nitril of nitric acid.

Mr. James Parkinson then read a paper "*On the Phosphide of Magnesium.*" The author described the formation of this body under a variety of circumstances and with the use of different kinds of phosphorus. He pointed out the error of employing carbonic acid for filling the apparatus prior to the volatilisation of the phosphorus and passage of its vapour over magnesium filings, as practised by Mr. T. P. Blunt; and denied likewise the stable character which had been attributed to the phosphide. Mr. Parkinson showed the case with which it decomposed water

(with brisk effervescence) at the ordinary temperature, and demonstrated the change into phosphide of hydrogen and hydrate of magnesia, which occurred as the result of drawing a current of moist air over the finely divided phosphide of magnesium. A small quantity of hypophosphite of magnesium seems also to be formed during the process of oxidation. The phosphide is described as a hard, brittle, difficultly fusible substance, steel-grey in colour, but usually exhibiting a dark brown exterior resembling the surface of a "clinker." Its analysis confirmed the formula previously given—viz., Mg_3P.

Mr. Spiller referred to the circumstances under which he had prepared the phosphide of magnesium, and to the fact of his having arrived at the same formula as that originally stated by Mr. Blunt, and now confirmed by the more exact experiments of Mr. Parkinson.

A large and very fine specimen of frozen glycerine was then exhibited by Dr. W. S. Squire, who stated that it was a portion of five tons of that article which he had imported from Germany during the severe weather of the past winter. It was packed in 8-cwt. casks, and the contents of all of them proved to be quite solid, and of a light brown colour, on their arrival in England. The sample exhibited was a portion which had not yet been liquefied; its snow-like aspect was due to the removal of the colouring matter in the process of draining off the liquid portion. No sugar or any other known crystallisable matter could be detected in the glycerine—in fact, no impurity whatever, excepting about 5 per cent. of water and a trace of colouring matter. The solid was slightly heavier than the liquid portion, their relative gravities being 1·268 and 1·26. The speaker had been unable to procure again solid glycerine by exposing the liquid drainings from this sample to intense cold in the laboratory; even a journey by railway to Edinburgh and back during the recent hard frost failed to have any effect in determining its crystallisation. Ice and salt, besides other freezing mixtures, had been tried, but with no other result than making it very viscid, and fragments of the solid dropped in did not lead to any result. Some of these facts had been already published by Mr. Crookes in the Chemical News,* but Dr. Squire felt sure that the inspection of such a chemical curiosity would be interesting to the meeting.

The President proposed a vote of thanks to Dr. Squire for bringing the subject so prominently to the notice of the Society.

Dr. De la Rue said he had observed the unusually low temperature of −6° Fahrenheit at West Drayton about the time of the transmission of the glycerine to Dr. Squire. He felt considerable interest in hearing of the manufacture of this substance in such large quantities, since he believed his late father was one of the first to call the attention of chemists to the expediency of economising the glycerine in the process of soap-making.

The President adjourned the meeting until the anniversary on the 30th instant, and announced that at the next ordinary meeting on April 4 Dr. Russell would read a paper "*On Gas Analysis.*"

ROYAL INSTITUTION.

A Course of Six Lectures "*On Coal Gas*," by Dr. Frankland, F.R.S. (Lectures V. and VI.—March 21 and 23, 1867.)

The Impurities—Injurious Effects of Carbonic Acid; of Ammonia—The Purification of Coal Gas—The Diluents—The Illuminants—Conditions involved in the Generation of Gas possessing high Illuminating Power—Temperature of Distillation—Comparison of the Metropolitan Gas Supply with that of other large Towns.

The subject of impurities, it will be remembered, was commenced in the fourth lecture. The lecturer now explained that carbonic acid was not only useless as an illuminant, but detrimental to the light yielded by the other constituents of the gas. It produced this result by oxidation of the hydrocarbons, and consequently was itself reduced to the state of carbonic oxide. During this reduction, heat was abstracted from the flame to the extent of 2732° Fahr., which of course greatly lessened the luminosity. Mr. Barlow, who investigated this subject, found that 1 per cent. of carbonic acid reduced the luminosity by about 7 per cent. (London gas at present contains about 2 per cent.) The effect of this impurity was illustrated by burning two flames side by side, one containing about 2, and the other 10 per cent. The difference in luminosity was very evident.

Nitrogen is found in all coal, and varies from ¼ to ½ per cent.; during the distillation, the hydrogen generated combines with it, forming ammonia. Ammonia, if existing in gas, would, during combustion, form water, nitrogen, and minute quantities of nitric and nitrous acids. By Act of Parliament, this impurity is not allowed to be present in gas in quantity sufficient to brown turmeric paper when submitted to its action for a minute; the gas supplied to the Institution browned turmeric paper in less than this time. With regard to the removal of ammonia, there is no difficulty, owing to its great solubility in water, but some manufacturers purposely leave it in, as it is believed to prevent the deposition of naphthalin in the mains.

Much attention has been paid to the removal of sulphuretted hydrogen, which is confessedly the worst of the impurities. Hydrated oxide of iron is now used for its removal, in the place of hydrate of lime, which was formerly used for the purpose.

The chief advantage of this change is that the hydrate of iron, after having withdrawn the sulphuretted hydrogen, may be reconverted into the hydrate by simple exposure to the air. After being used a great many times the material is distilled to utilise the sulphur it contains.

Though the employment of hydrate of iron is a saving to the manufacturer, the quality of the gas is worse in two respects than when the hydrate of lime is used. The latter purifier separates carbonic acid as well as sulphuretted hydrogen, and the compound formed with the sulphuretted hydrogen is capable of uniting with and withdrawing a certain quantity of bisulphide of carbon from the crude gas.

A new process for determining the amount of sulphur in coal gas has lately been devised, which gives nearly double the amount obtainable by the method at present used. A table giving the results of a number of trials, in which the sulphur was estimated by the ordinary methods, showed in a large number of cases more than 20 grs. of sulphur to the 100 cubic feet (the maximum amount allowed by Act of Parliament); and, according to what we have already recorded, this only represents about one-half of the amount present! Dr. Frankland explained that the Act of Parliament was perfectly inoperative. Gas is impoverished in illuminating power by transmission through long systems of mains, partly by the condensation of previously vaporised hydrocarbons, and partly by the exchange of hydrogen for atmospheric air by diffusion. The diluents contribute indirectly to illumination—in the first place, by taking up volatile hydrocarbons in the state of invisible vapour. An experiment in illustration of this fact was made thus:—A supply of hydrogen was divided into two portions, and one portion during its passage to the flame came in contact with tow soaked in benzol; the luminosity of the latter was in striking contrast to the feebleness of the hydrogen flame.

Secondly, one of the diluents, marsh gas, under peculiarly favourable circumstances, may become an illuminant. A flame supplied with ordinary marsh gas was compared with one burning marsh gas which had been passed through a tube heated in a charcoal furnace.

* *Vide* page 26 of the present volume.

The following facts (exhibited in a diagram) are some of the most important in reference to the diluents:—

1 cubic foot of hydrogen, at 60° F. and 30 in. bar., consumes ½ cubic foot of oxygen, generates no carbonic acid, and heats 1 lb. 13 oz. of water from 32° to 212° F., or 2500 cubic feet of air from 60° to 66·4° F.

1 cubic foot of carbonic oxide, at 60° F. and 30 in. bar., consumes ½ cubic foot of oxygen, generates 1 cubic foot of carbonic acid, and heats 1 lb. 14 oz. of water from 32° to 212° F., or 2500 cubic feet of air from 60° to 66·6° F.

1 cubic foot of marsh gas, at 60° F. and 30 in. bar., consumes 2 of oxygen, generates 1 of carbonic acid, and heats 5 lb. 14 oz. of water from 32° to 212° F., or 2500 cubic feet of air from 60° to 80·8° F.

The illuminants contained in coal gas were given as the following:—Olefiant gas (ethylen), propylen, butylen, caproylen, acetylen, benzol, toluol, cymol, &c.; also hydrides of hexyl, octyl, and decyl.

Nearly all the illuminating power resides in the ethylen series. To prove this, gas containing the bodies given above was brought in contact with bromine (which absorbs this series). After this treatment there was scarcely any luminosity.

Acetylen is always a constituent of coal gas. It may be produced in various ways. Marsh gas yields acetylen when submitted to a high temperature. Coal gas, by the action of the induction spark, was shown to yield acetylen. M. Berthelot's process of combining the elements directly, and Mr. McLeod's process of burning air in coal gas, which yields acetylen in quantity more readily than any of the others, were brought forward. The production of the red acetylide of copper, and its explosiveness were both exhibited. The great value of acetylen as an illuminant was shown by experiment.

With regard to the temperature of distillation, a cherry-red heat was said to be the proper temperature; higher than this the volume of gas is increased, but is of worse quality; a lower temperature gives too small a volume of gas. A table comparing the cost of gas with other illuminating materials for the same amount of light showed the great economy of gas over them all.

In conclusion, Dr. Frankland remarked on the bad quality of the gas supplied to London. He thought the public were not fairly treated by the gas companies. Sixteen years ago he had examined the London gas, and now he found it to be considerably worse than it was then. Had there been no improvements in this direction since that time? Undoubtedly there had, and any invention which decreased the cost of manufacture was eagerly seized, but those relating to improving the quality of the gas were entirely ignored. To obtain the same amount of light in London as is obtained in Edinburgh, it is necessary to burn twice as much gas, to put up with twice as much heat caused by its combustion, and to inhale ten times as much sulphurous acid. No gas ought to be considered good enough for use which did not give a light equal to twenty standard candles when burning 5 cubic feet per hour.

QUEKETT MICROSCOPICAL CLUB.

The monthly meeting was held at University College on the 22nd inst., Ernest Hart, Esq., President, in the Chair.

A paper was read by Mr. C. A. Watkins on "*Yeast and other Ferments.*" The matter was treated broadly, and the author explained the similarity of the chemical operations of all ferments, whether they be living organisms, as yeast, or substances derived from organic sources, as albumen, casein, diastase, &c., and urged the necessity of considering these operations together, rather than separating them into those which are the results of organic growth and those which appear to be simply chemical actions. The changes in each fermentation were indicated by a diagram of the chemical formulæ. In describing the transformation of starch into sugar, sugar into alcohol, &c., he pointed out the albuminous character of the ferments, and showed how necessary such matters are for the healthy growth of yeast; and in describing the viscous, lactic, and butyric acid fermentations, and also the ordinary conversion of alcohol into vinegar, he called attention to the universal appearance of the minute Bacteria and Vibriones which accompany these changes, and invited microscopists to the study of these low forms of life, that some light may be thrown on the relation they evidently bear to the various phases of decay of organic products generally.

Ten members were elected, and the proceedings terminated with a *conversazione*.

ACADEMY OF SCIENCES.

(From our own Correspondent.)

March 18, 1867.

M. Henri Sainte-Claire Deville communicated some quite new experiments by M. H. Debray in order to demonstrate that chemical decomposition is analogous to the evaporation of a liquid in this sense—that the tension of the gas proceeding from the decomposition is constant. He operated upon pure carbonate of lime, Iceland spar, or ordinary impure carbonate of lime, placed in the middle of a tube communicating sometimes with a mercurial pump and sometimes with a gauge apparatus for measuring the tension of the carbonic acid disengaged by the decomposition. The carbonate was alternately submitted to four constant temperatures—360° C. vapour of mercury, 440° vapour of sulphur, 660° vapour of cadmium, 1040° vapour of zinc. It was found that at 360° the vapour of the carbonic acid was absolutely *nil*; at 440° it was hardly sensible; at 660° it was only 85 millimetres; at 1040° it attained 551 millimetres. Under each of these temperatures the tension was also constant, and the results remained the same when they passed from the pure carbonate to the impure.

Equally curious researches by M. Jules Regnauld, and also presented by M. Sainte-Claire Deville, were made in order to resolve these two questions:—1. Is the union of thallium with mercury accompanied by a disengagement or an absorption of heat? 2. Is amalgamated thallium more or less electro-positive than pure thallium? Very accurate experiments gave the following results. There is elevation of temperature, and thus a disengagement of heat, during the formation of the amalgam of thallium and mercury. Pure thallium is electro-positive to the amalgamated thallium. The experiments of M. Regnauld prove that the position of thallium is remarkably lower than that which separates cadmium from zinc in the Daniel couple. They confirm this general proposition—"Every time that a metal is united to mercury, the place which it occupies in the scale of affinities is modified, and thermo-phenomena are observed."

M. Blanchard presented a *crab*, of a species which is found on our coasts, brought from Japan, and from the collection of Von Siebolt, which had attained a gigantic size. Its arms measure 1·20 m.; its breadth across the claws is more than 2 metres. For the crustacea, it is not full-grown; the development increases with the age, and if the sea is very calm the proportions it takes are enormous.

M. Jansen, who went to Tarni, in the Kingdom of Naples, to observe the annular eclipse of the sun on March 6, has proved that the spectrum of the annular rays did not contain more black lines than that of the full sun.

M. Duboscq presented a new photographic planchette by M. Auguste Chevalier.

M. Dumas presented nodules of anthracite, obtained by the Count de Douchet, almost as hard as the black diamond; it is composed of carbon 97, hydrogen 0·50, oxygen 1·50; its specific gravity is 1·65.

M. Louis Daniel, Professor of Physics at the central School of Arts, communicated a curious experiment on the transporting of substances by the voltaic and induction current. It is generally admitted that the current of the pile moves, in the interpolar circuit, from the positive to the negative pole. The existence of a mechanical action exerted in this direction is confirmed by the movement produced in the carbon by the voltaic arc. It is evident, also, from the difference of level which takes place, under the influence of a current, in a vessel divided into two compartments by a porous diaphragm, and enclosing a liquid of weak conductivity, which, at the commencement of the experiment, presents two surfaces of equal height at each side of the separation. This movement of the liquid by the current, discovered by Porret, has been examined by Messrs. De la Rive, Becquerel, and latterly by Windemann, who has determined its laws under certain conditions.

It is possible to place in evidence this action of electricity, and to show the direction by an experiment more simple than the preceding. If we electrify water in a glass, of which the bottom is rather wide, rounded in the middle, and if a drop of mercury be dropped in, it will be seen that the globule runs away from the positive electrode when it is pushed towards it. Thus, by properly displacing the electrode, we can give to the electrode a movement of rotation. It is the observation of this phenomenon which has led him to the experiment which M. Daniel describes. He fills with slightly acidulated water a glass tube of any length, and of a diameter from ten to fifteen millimetres, bent at a right angle at its two extremities. He introduces into the liquid column a globule of mercury two or three centimetres long, and he plunges into the two vertical portions the electrodes of a more or less powerful pile. By means of the globule of mercury he easily levels the instrument.

As soon as the current passes, *the globule becomes elongated* and *begins to move; it goes from the positive to the negative pole.*

If, by means of a commutator interposed in the circuit, the direction of the current be changed, the globule *stops and immediately takes an opposite direction*, always from the positive to the negative pole.

By properly manœuvring the commutator, we can make the mercury take an indefinite alternating motion. The ends of the globule, under the influence of the current, do not present the same appearance. It is brilliant towards the negative electrode, and dull towards the positive one. This is owing to its being polarised like the whole column of the liquid; it possesses positive tension in front and negative tension behind. The oxide of mercury formed during the experiment is collected at the negative end, and is reduced, at least in part, by the hydrogen produced at the same time. If the liquid contain too much acid, a salt is formed which disturbs the transparency of the column, and bubbles of hydrogen are disengaged. When the direction of the current is altered, a sort of veil which covers one of the extremities of the globule is seen to fly to the other extremity.

Four Bunsen elements suffice for this experiment if we employ a tube 0·40 m. to 0·50 m. long. With twenty-four elements we can operate upon a tube a metre long. The current of fifty elements gives too great a velocity to the mercury, and breaks it up into globules which travel in the same direction. When the tube is inclined, the mercury can still move from the lower to the upper end. Thus, the weight of the mercury being known, we can form a very clear idea of the work performed by the portion of the current which traverses the globule. If the inclination be progressively augmented, a moment arrives at which the equilibrium is established between the force of the current, which tends to make the mercury ascend, and the action of the weight, which causes it to descend, the globule rests stationary, but it is elongated. It is always subject to a very apparent interior movement, and it takes a rotatory motion, first in one direction, then in another.

The same experiment can be made by means of a Ruhmkorff's coil. As the currents furnished by this apparatus are alternately in contrary directions, a commutator is necessary in the interpolar circuit, so as to suppress the inverse current. It is important to remark that the conductivity of the transported material is one of the necessary conditions of the movement; a globule of sulphide of carbon introduced into the tube is insensible to the passage of the current.

In this experiment it is a mechanical action exercised by the current which produces the movement of translation; the pressure exerted by the hydrogen which is disengaged at the negative end of the globule acts a prominent part in this phenomenon.

NOTICES OF BOOKS.

Photographs of Eminent Medical Men. Edited by Wm. Tindal Robertson, M.D., M.R.C.P. Photographic Portraits from Life, by Ernest Edwards, B.A. Cantab. London: J. Churchill and Sons, New Burlington-street; Ernest Edwards, 20, Baker-street, Portman-square, W. Volume II., No. 1.

The second volume of Photographs of Eminent Medical Men commences very well; each part of the work (price 3s.) contains three excellent photographs, with a contemporary notice, of from two to six pages, of the eminent men whose photographs are given. The success of such memoirs must depend (as the late editor remarked) upon "the exclusion of all controversial passages and of all such details as belong only to private life." The present editor, Dr. Robertson, sees no reason why a brief sketch of some of those who have recently passed from amongst us should not be introduced into the series. That there can be no such objection will be allowed by all who read the biographies of this kind that appear in the *Proceedings* of the Royal Society. There is a fellow series to this one also published, "Photographic Portraits of Men of Eminence in Literature, Science, and Art," in the back numbers of which have appeared notices of Faraday, Tyndall, Miller, Graham, De la Rue, and other eminent chemists; also Dr. William Farr, Sir J. Clark, Dr. Latham, and other physicians; while we find the following names in succession: Sir De Lacy Evans, Professor Partridge, Martin Tupper, and the Lord Bishop of Lichfield,—a very instructive association of great names in literature, science, and art. We would urge the editor to avoid encroachments upon this work which we have just noticed, the photographs of which are taken by the same artist; for if the schemes of the two series are kept distinct from each other room will be left for future ones to appear without repetition. Portraits contained in the literature and science series, as those of Sir James Clark and Sir William Fergusson, would be more judiciously placed in that of "medical celebrities," for their fame is of a medical character; while those of Professor Huxley and Dr. Bence Jones should appear in the former rather than in the latter work, from their discoveries being mostly made in quite different fields. Lastly, for the success of this work to be complete, we would remind the editor that portraits are announced of eminent medical men of all countries. The present Part contains portraits of Professor Huxley, Dr. Bence Jones, and Dr. Cowan; the next will give us portraits of Mr. Lawrence, Dr. Gardner Hill, and Dr. Ranking. Excluding the first two as not being strictly medical, we would suggest that, great as are the names of the other gentlemen in the list, and world-wide as may be their reputation, there are also foreign names, as those of Civiale, Skoda, Trousseau, that are certainly quite as well

known, and in the first two parts of Volume II. eminent medical men *of all countries* are not properly represented. These things, however, admit of very easy remedy, and we are sure that the justice of our remarks will be recognised; and when we call to mind the fact that on the Continent, in museums and libraries, our own scientific celebrities are so frankly recognised and placed in such flattering company, such exclusion of foreign physicians almost appears a want of courtesy. Two out of the three portraits of the present Part, about which we can give any opinion, are excellent; we allude to those of Professor Huxley and Dr. Bence Jones. Of the latter gentleman we know of none better. The memoirs are also valuable, from their clearness of expression, and conciseness at the same time. We could place fuller reliance upon the information supplied if we were more assured of its accuracy in every case: *e. g.*, in speaking of Professor Huxley, the editor says, "in 1845 he took the degree of M.B. at the University of London, with honours in physiology;" wheas the truth is that in the *Calendar* Mr. Huxley figures only as an undergraduate. Many of our readers owe much to this eminent teacher at the Royal School of Mines, and we can recommend this portrait to them. That of Dr. Bence Jones, whose name is so closely connected with English chemistry generally, and the Royal Institution especially, cannot fail to be interesting to all of them. We should think that there is at the present time a good opening for a series of eminent chemists, and to no one could the execution of the portraits be more safely entrusted than to Mr. Ernest Edwards.

Chemical Manufactories Directory of England. 1867. London: Kent and Co., Paternoster-row. Price 2s. 6d.

This directory appears for the first time, and the manufacturers of England are alone enumerated, no mention being made of the Irish and Scotch works. It contains twelve pages of addresses and three more for the index, one for the preface and contents, one for advertisements. Its price is half-a-crown! and it certainly would not be a cheap book if sold for sixpence. The specialties of the manufacturers are also given. From this we learn that Messrs. Condy are manufacturers of *various sanitary chemicals*. Another chemist makes creasote and *carbonic acid*.

CONTEMPORARY SCIENTIFIC PRESS.

[Under this heading it is intended to give the titles of all the chemical papers which are published in the principal scientific periodicals of the Continent. Articles which are merely reprints or abstracts of papers already noticed will be omitted. Abstracts of the more important papers here announced will appear in future numbers of the Chemical News.]

CORRESPONDENCE.

Standard Thermometers.

To the Editor of the Chemical News.

Sir,—As a letter written in error to the *Times* on Jan. 16 relative to a thermometer sold by us to the Rev. Cooper Key has given rise to a lengthened correspondence in your journal, we think it but right that you should know how the affair has terminated, and, without troubling you with a long letter, we will simply give an extract from the Rev. C. Key's last communication, in reply to a letter sent to him on March 15. He says:—

"Gentlemen,—Your letter of this morning has much surprised me, as I had concluded long ago that Mr. Glaisher had informed you of the course I had already taken, which was to write to the *Times* explaining my original error in comparing the two instruments, stating I had sent the instrument to Kew in order to set the matter of its true corrections at rest, and giving the table of those corrections."

The following is a copy of a letter received from the Kew Observatory:—

"Kew Observatory, Feb. 16, 1867.

"Dear Sirs,—On my return from the North this morning, Mr. Whipple has informed me of a correspondence he has had with the Rev. H. Cooper Key and yourselves regarding the accuracy of your thermometer No. 7381 maximum. It appears that Mr. Key, having compared this instrument with a thermometer verified at Kew, thought he noticed a much greater difference in the two instruments than the correction for No. 7381, furnished by Mr. Glaisher, would have led him to suppose. In

other words, he thought he had discovered a difference between the methods of testing thermometers pursued at Greenwich and at Kew. Mr. Whipple and Mr. Baker, assistants at Kew, and your Mr. Zambra, made the comparison of the instrument with the Kew standard, and found a result agreeing as nearly as possible with that of Mr. Glaisher. Mr. Key has been induced to repeat his observations, and in a letter subsequently received by Mr. Whipple from him he mentions that he has obtained results agreeing with those found at Greenwich and at Kew. "Yours very truly,

(Signed) "B. Stewart.

"Messrs. Negretti and Zambra."

From the above it will be seen that the problem of $2\frac{1}{2}°$ index error which is being discussed by your readers is best solved by the simple fact that it did not exist at all.

We are, &c.

MM. Negretti and Zambra.

To the Editor of the Chemical News.

Sir,—My letter to you about Standard Thermometers has called forth some counter remarks from "A Subscriber," and you will perhaps kindly allow me a small share of your valuable space for a reply. The gist of "A Subscriber's" letter is—first, that the explanation adduced by me for the index error of thermometers is not new; and, secondly, that it is not sufficient. Now, I claimed by no means novelty for the explanation given in my letter; on the contrary, I mentioned it as perfectly well known, just because "A Subscriber" said in his first letter that Mr. Pastorelli "believes this increasing error owing to the contraction of the glass after its manufacture," which, taken in conjunction with the rest of the paragraph, seems to be given as a novel explanation.

As to the second part, "A Subscriber" contends that the one-sided pressure of the atmosphere and the molecular change brought about in the glass by the heat and force of the boiling mercury (that I meant this he sees very well himself, and he might accordingly have left out the first part of his letter containing a refutation of an opinion not at all held by me) are not sufficient to account for the extent of error—viz. 2° (C. or F.?) He refers me, in that respect, to "books," without mentioning any in particular; to some nameless practical manufacturer who computes the amount of the one-sided pressure only at 0·4°; and to observations of his own, apparently published nowhere, as to the influence of the boiling mercury on the glass. Perhaps he is right; but who can be convinced of that by those vague references without chapter and verse? As far as I am concerned, I have the least possible objection to be convinced, and to learn from the "Subscriber's" and Mr. Pastorelli's experiments; but so long as those are not published they can scarcely be claimed to be authoritatively decisive on such a nice experimental subject on an anonymous assertion. I should be as thankful for their publication as any one, and I heartily join in your desire expressed at the close of "A Subscriber's" letter. I am, &c. G. L.

Sulphate of Soda in Glass-making.

To the Editor of the Chemical News.

Sir,—The vast plains covered with sulphate of soda were given by the Government to particular persons. A great deal of this useful mineral lies in plains, and frequently covers the banks of lakes. The rough sulphate of soda, or gudjir, is employed in Transbaikal principally for soap and glass fabrication. Being on the glass manufactory near Irkoutsk, belonging to the merchant I. G. Schwedoff, we spoke about the properties of gudjir. I am now occupied with its analysis; he tells me that, notwithstanding all efforts and experiments made for decolouring the glass mass, the green bottle-colour appears very strong. Now, Sir, I beg you humbly to indicate to me the manner of decolouring the glass, or a practical method of completely separating the protoxide and oxide of iron. What is the price of 1 kilogr. of titanium, and for what purpose is it employed in glass fabrication? How to augment the colouring quality of peroxide of manganese? In small quantities it does not act, but being employed in a greater quantity the gudjir glass appears a black-reddish.

I am, &c. A. Lomonossoff,

Civil Officer of General Governor of East Siberia.

Irkoutsk, East Siberia, February $\frac{22}{10}$, 1867.

[If some of our readers will kindly give the information asked in the above communication, we shall have great pleasure in forwarding it to our Siberian correspondent. —Ed. C. N.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Urea: its Constitution.—H. Kolbe. Urea is ammonia in which H_1 is replaced by carbamyle $(C_2O_2,H_2N)'$; it is metameric with carbamide, a diamine in which H_2 are replaced by $(C_2O_2)''$. Although ammonias in which hydrogen is replaced by an oxacid radicle are indifferent bodies or weak acids—an observation which renders it probable that carbamide is an indifferent body—yet amido derivatives of even strong acids possess basylous properties, so that we need not be surprised that urea is capable of uniting with acids. Urea results from the union of two molecules of water and one molecule of cyanamide, the cyanogen in the latter body interchanging elements with the water to form carbamyle: a simple change in the position of the elements converts ammonic cyanate and also carbamide into urea. Ethylic carbamate reacts with ammonia to form urea and alcohol in a manner precisely analogous to that in which other compound ethers interact with ammonia. Biuret is ammonia in which H_2 are replaced by two molecules of carbamyle; the usual view that it is a triamine has little probability. Compound ureas formed by the action of primary or secondary ammonias on cyanic acid, or its compounds with alcohol radicles, arise from the replacement of hydrogen in the ammonia by a primary or secondary carbamyle formed by the union of that hydrogen with the cyanic acid or its alcohol radicle compound; hence, if the secondary ammonia employed—*e.g.*, triethylamine—contains no such replaceable hydrogen, an urea cannot be formed by it, a conclusion supported by experiment. But if urea be carbamide there seems no reason why triethylamine should not give triethylurea as easily as diethylamine gives diethylurea. It will be seen that, according to the theory here propounded, the urea resulting from ethylic cyanate and ethylamine is isomeric with, but different from, that formed by cyanic acid and diethylamine; and experiment shows that, if boiled with potash, the former gives ethylamine, and the latter diethylamine. Experiments are in progress to decide whether both the typical hydrogen atoms in urea are directly replaceable by ethyl. The application of the above views to the formation of ethylene urea from cyanic acid and ethylene diamine is simple.

Kreatine is urea in which one typical hydrogen atom is replaced by the radicle of methylamidacetic acid (sarkosine), and experiment shows that if kreatine is boiled with baric hydrated oxide it is split into sarkosine and urea; if the converse reaction to that which produced urea from cyanamide be hypothesised, the formation of kreatinine from kreatine occurs by splitting the carbamyle in kreatine into cyanogen and water, and kreatinine becomes cyanamide, having H_1 replaced by sarkosine.—(*Zeitschr. Chem.*, N.F., iii. 50.)

Nitric Acid, Density of (O=8).—J. Kolb. A number of determinations taken at different temperatures

showed that the maximum contraction of nitric acid corresponds exactly with NO_5+7HO : the coefficient of expansion between 0° and 15° is 0·001263—about three times that of water. The density was taken by sp. gr. bottle, and the quantity of acid determined by adding to the diluted acid an excess of dried and weighed calcic carbonate, the undissolved residue of which was weighed back. A table partly interpolated accompanies the paper. —(*Ann. Chim. Phys.*, S. 4, x. 136.)

Bichlorodi-isopropyl (C = 12).— C. Schorlemmer. The body obtained by acting on di-isopropyl with chlorine in presence of iodine is $C_6H_{12}Cl_2$.—(*Zeitschr. Chem.*, N.F., iii. 75.)

Aceto-silicic Anhydride (C = 12, O = 16, Si = 28).— Friedel and Ladenburg. To a mixture of monohydrated acetic acid and acetic anhydride rather less than the proportional quantity of silicic chloride is added; the mixture is boiled as long as chlorhydric acid is evolved; on cooling the anhydride crystallises out, and, after washing with anhydrous ether, is pure. It is the first crystallisable organic compound containing silicium. It is white, decomposes at about 165° under normal pressure, but may be distilled at a pressure of five or six millim. at 148°; it melts at about 110°. Its formula being $SiO_4(C_2H_3O)_4$, it corresponds exactly to Ebelmen's ethylic silicate, $SiO_4(C_2H_5)_4$.

Friedel and Crafts described (*Ann. Chim. Phys.* [4], ix. 5) an ethylic derivative of this anhydride of the constitution $SiO_4(C_2H_5)_3(C_2H_3O)$, obtained by heating ethylic silicate with acetic anhydride. (*Comptes Rendus*, lxiv. 84.)

Thiosinamine, some derivatives of (C = 12, O = 16). —Dr. R. L. Maly. By adding a slight excess of bromine to an alcoholic solution of thiosinamine and concentrating the solution, crystals are obtained soluble in alcohol and water, fusing at 146° to 147°, having the composition $C_4H_8N_2SBr_2$, and a name thiosinaminic bibromide. If a known quantity of this body is shaken with a known quantity of fresh argentic chloride in water, the silver compound washed and weighed, and the quantity of bromine in it calculated, it is found that one-half of the bromine in the organic compound has been replaced by chlorine with production of thiosinaminic bromochloride, crystallisable from alcohol, fusing at 129° to 130°, and containing a group BrCl with the functions of a hydracid. The bibromide combines with platinic chloride, and, if treated with auric chloride, forms a yellow precipitate, which in a few seconds becomes purple and crystalline, with an accompanying exchange of bromine and chlorine between the metallic and organic bodies, the final result being $C_4H_8N_2SBrCl.AuBr_3$, which, when crystallised from hot water, is a very fine but unstable body.

Bromothiosinaminic hydrated oxide is made by decomposing thiosinaminic bibromide with argentic hydrated oxide; it is uncrystallisable from water, bitter and astringent, and strongly alkaline; it is decomposed by chlorhydric acid, thiosinaminic bromochloride being produced.

Thiosinaminic bibromide may be viewed as ammonic chloride in which HCl is replaced by BrBr; if treated with cold concentrated sulphuric acid, bromhydric acid is given off, the hydrogen of which is evidently derived from the sulphuric acid. Passing now to the more simple body ammonic chloride, and examining its behaviour with sulphuric acid, it is seen that the chlorhydric acid evolved may be supposed either to exist as such in H_3N,HCl, or to be produced by the mutual action of $2(H_4NCl)$ and H_2SO_4. Analogy suggests that the latter is the more correct view. (*Akd. z. Wien*, 54 [1866]).

Glass.—J. Pelouze. Glass containing a very large proportion of silica is remarkable for the ease with which it becomes devitrified by heat; such a kind of glass was found to have a low refractive power, but about the same dispersive power as ordinary crown of St. Gobain. Glass containing alumina is by no means readily devitrified; it is generally coloured, because lime necessary to take up the alumina, if in any quantity, forms with it a compound which attacks the crucibles. It appears to be of low refractive power. Glass containing magnesia is even more easily devitrified than highly silicated glass. Glass is probably an indefinite mixture of definite silicates. Glass containing small quantities of ferrous oxide and sodic sulphate, when exposed for some time to direct sunlight, becomes slightly yellow from oxidation of the ferrous oxide to ferric, with accompanying reduction of sodic sulphate to sulphide; a dull-red heat re-establishes the former state of equilibrium, and the glass becomes colourless; This change may be alternated any number of times; a temperature below that of annealing will not decolorise the yellow glass. It has been shown in a former memoir that carbon, silicium, boron, even hydrogen, will, by reducing the sodic sulphate generally present in glass, produce a yellow colour. On the other hand, glass containing ferrous oxide and coloured yellow at high temperatures by reduction of sulphates or direct addition of sulphides, remains coloured in annealing, because the iron is not in a condition to oxidise the sulphide to sulphate. Faraday in 1824 observed the coloration by sunlight of glass containing manganese. This phenomenon occurs whenever ferric and manganous oxides are in presence in glass; annealing, by causing a return to the iron of the oxygen transferred by it, under the sun's influence, to the manganese, destroys the amethystine colour. Yet, again, a sample of glass which would become violet by exposure to sunlight also becomes coloured if taken from the furnace and suddenly cooled, or if the annealing be omitted. Is there, then, a temperature intermediate between that of fusion and that of annealing which can produce the same effects on the glass as would be produced by sunlight?—(*Ann. Chim. Phys.*, S. 4, x. 184.)

Ammonia, Determination of.—Prof. A. Vogel. Determinations of ammonia in soils, &c., by alkalies proper, lime, or baryta, are generally too high, from the decomposition of nitrogenised compounds other than ammoniacal. Boussingault showed that freshly burnt magnesia exercised no such injurious power. To reduce this observation to practice, the substance to be examined, mixed with freshly ignited magnesia, is placed, accompanied by a known quantity of sulphuric acid, under an air-tight glass cover. The excess of acid remaining after several days' repose may be determined in the usual way. —(*N. Repert. Pharm.*, xv. 489.)

Ketones Compound (C = 6, O = 8). — G. Wischin. Phtalic chloride dissolved in benzol reacts with zincethyl to form phenylene-diethyl-acetone

$$\left.\begin{matrix}(C_{12}H_4)'' \\ (C_4H_5)_2\end{matrix}\right\}\left[\begin{matrix}C_2O_2 \\ C_2O_2\end{matrix}\right]$$

which crystallises from ether and melts at 52°. Succinic chloride gives in like manner ethylene-diethyl-acetone, a liquid of nasty odour, heavier than water, decomposing on heating, and having the composition

$$\left.\begin{matrix}(C_4H_4)'' \\ (C_4H_5)_2\end{matrix}\right\}\left[\begin{matrix}C_2O_2 \\ C_2O_2\end{matrix}\right]$$

Both are indifferent bodies. Experiments are being made to convert them into the corresponding alcohols.—(*Zeitschr. Chem.*, N.F., iii. 46.)

A New Thallium Mineral.—We hear that a selenide of copper, silver, and thallium has been found in Norway and analysed by M. Nordenskiörd. It contains 17 per cent. of thallium.

Medlock's Patent for Red and Purple Dyes.—We learn from the Commissioners of Patents' *Journal* that this patent, No. 126, dated January 18, 1860, has become void by reason of the non-payment of the additional stamp duty of 100*l.* before the expiration of the seventh year from date.

MISCELLANEOUS.

Sanitary Reform League. — We learn that a Sanitary Reform League has been established, for the purpose of bringing the force of public opinion, and, if need be, the power of the State, to bear upon the local authorities throughout the Kingdom; and further, if found necessary, of endeavouring to induce the Legislature to render more stringent the existing enactments relating to public health. The League already numbers among its members many gentlemen in London, Manchester, Liverpool, Leeds, and other towns. It is intended shortly to hold a conference in London, at which several eminent scientific men and members of Parliament, including some who have been active in framing or promoting sanitary legislation, have promised their attendance, to determine in what manner the objects of the League can be most efficiently attained.

Extract of Meat.—The food sub-committee of the Society of Arts are doing a very valuable service to the nation at large by their investigations which are now being instituted, and the evidence of Dr. Thudichum is not only interesting, but instructive, from the soundness of chemical knowledge displayed by it. Since the question is even now being discussed, before giving an abstract of the valuable evidence we have alluded to, we should like to ask some questions upon matters that have at present escaped due attention. If good beef-tea and extract of meat have such small nutritive power, containing, as they do, the creatine and salts, is it not probable, as has been before repeatedly asked, that they may possess the property, like tea and coffee, of diminishing the waste of the tissues? Does Dr. Thudichum know of any accurate determinations of the quantities of urea secreted by a patient with a diet of beef-tea, when suffering from diseases where the waste is in such great excess to the produce; and has not the question of prevention of waste much to do with that of nutritive food generally? An eminent Physician (Dr. Tanner) is our authority for the following:—"It has been proved that dogs die slowly if fed upon bread and gelatine alone, but when greatly reduced by this diet they soon regain flesh and strength if two ounces of meat-tea be daily added to it." We suppose that here a carnivorous animal is fed by gluten and starch, and waste is prevented by the chemical bases contained in the meat extract. Another thing that we should like to have had mentioned is the value of oatmeal as a substitute, in great part, for meat. It certainly is the main part of the food of one of the most vigorous people in the world. Perhaps oatmeal and extract of beef—if the latter be procured in sufficient quantity—would be one of the cheapest nutritious diets available for the lower classes, and an education in cookery would hardly be an essential for its preparation. Mr. Philpot, as it will be seen, who was in the habit of melting down 1000 to 1500 sheep daily in Australia, said that he had tried in vain to discover any process by which meat could be preserved except as an extract, as by Liebig's method. It is only rational to suppose, too, that the Extract of Meat Company would be enabled very greatly to reduce the price, if the demand were once established for a larger supply. We may mention that Professor Gamgee's method for the preservation of meat, mentioned in the Chemical News of March 15, 1867, will be submitted to a most rigorous trial. Dr. Thudichum's evidence is an epitome of the chemistry of meat, and the note that we append contains nearly the whole known by chemists about the matter. The object of the question first put to Dr. Thudichum was to ascertain whether it would be justifiable for the committee to recommend to the Government or any other public body the institution of experiments to show whether these preserved meats could become an entire or partial article of diet. At a former meeting the following had been considered:—Raw meat from South America preserved by Dr. Morgan's process; same by the paraffin method of Professor Redwood; Dr. Hassall's flour of meat—none of which were entirely approved of as substitutes for meat; and, lastly, Baron Liebig's extract of meat, the merits of which then called for examination. In reply to inquiries, Dr. Thudichum remarked—"Extract of meat lacks the essential properties of nutriment. There is a prevalent, but erroneous, opinion that extracts of meat, particularly that prepared on Dr. Liebig's plan, are nutritious. Tea and coffee will not nourish a man, but both tea and coffee are strong stimulants of the nerves of the heart and of the brain, and it is likely, I think, that the extracts of meat contain a substance which is somewhat similar in its effects to these stimulants. That is the view, I believe, that Liebig himself takes of his extract. If the committee desire to know whether I should recommend them to have experiments made upon the extract of meat of Liebig, I must answer that I do not see that any experiments are necessary unless they wish to open the entire question—What is the sense of our drinking beef-tea or drinking broth? There is so little nutriment (in it) that if you dissolve a teaspoonful of the extract in a cup of water and drink it, you will not receive so much nutriment as you would derive from a single mouthful of meat. Beef-tea seems to have an important effect, but the effect is not in the sense of nutriment; it is due to the specific effects of certain ingredients, especially creatine, the action of which in some degree resembles that of theobromine. Again, in beef-tea are potassium salts, which the body requires for the production of muscular power; potash is as essential an element in the chemistry of muscles as in that of the blood. Then, again, there are contained in beef-tea certain acids, of which lactic acid is one, and inosic acid another. If there is an absence of flavour in any kind of meat, lactic acid, if mixed with the gravy during preparation, acts as a substitute, and produces a relishing flavour, the fine flavour of meat; the osmazome which provokes appetite is due in part to the action of this lactic acid. We have to rely on these principles for an explanation of the efficiency of beef-tea, creatine, and creatinine, paralactic acid, inosic acid, inosite, and potassium salts—which are essential and which not, we cannot at present say. Too strong a solution of extract of meat is as bad as too strong tea or coffee." In answer to the chairman (Right Hon. H. A. Bruce, M.P.)—"Salt meat being an imperfect food, may I ask you whether this extract of meat would form a complement to that?"—Dr. Thudichum says: "I do not think so, because salt meat has been deprived of a certain amount of albumen. However, the loss of nutritious value from salting meat is not very great on the whole." As regards the nutritive qualities in meat itself which the extract does not contain, we find the following list of substances in fresh meat:—First, albumen; then syntonine. When we mince meat and extract the albumen by means of water, there remains this syntonine undissolved; but when mixed with dilute acids it becomes a thin jelly, and is afterwards dissolved. Then myochrome, the colouring matter contained in the muscles—this is chemically identical with the colouring matter contained in the blood. The use of this latter is to take up oxygen, and so oxidise the noxious products of the spontaneous decay of albumen, giving out carbonic acid. If the meat were shut up close after being killed, it would become putrefied in a few hours. This myochrome is a compound body containing a quantity of iron; it is dissolved with the albumen, and precipitated with it during boiling. Lastly, very little gelatine as well. Then the constituents as before mentioned of beef-tea, with a brown syrupy matter which is not more definable at present. Inosite is a kind of sugar met with in French beans, also contained in muscle and in beef-tea. An occasional product is animal dextrine, or hepatin, or glycogenic

substance from the liver. Sometimes in working half a hundredweight of meat the chemist may get a pound of this matter; at others he may not obtain a trace. When beef-tea is made, the albumen and myochrome of the meat are made insoluble by boiling; the syntonine also is undissolved. After straining there is nothing left in beef-tea but inosite, creatine, creatinine, lactic and inosic acids, potassium salts, brown syrupy matter, and occasionally glycogen; but the latter would probably be absent from the extract as prepared by Liebig's Company. Of the from 7 to 10 per cent. of soluble solid matter, 4 to 4½ become again insoluble by boiling, so that it is not far wrong to say that only from 3 to 5½ out of 25, or from $\frac{1}{5}$th to $\frac{1}{8}$th of the whole of the solid constituents of meat pass into extract or beef-tea. From $\frac{4}{5}$ths to $\frac{7}{8}$ths of the solids are rejected. This concludes the first part of Dr. Thudichum's evidence, and the reader will see that in the above answer to the question, "What nutritive qualities are there in meat itself which the extract (*i.e.*, Liebig's extract) does not contain?" the extract is taken as being identical with beef-tea as ordinarily prepared, with the assumption of sundry boilings, &c. The whole answer does not turn, as it should do, upon what is there in meat not in the extract of meat, but what substances there are not in badly prepared beef-tea that are found in good meat.

Chemical Dreams.—At the February meeting of the Massachusetts Institute of Technology, M. Fleury, of New York, explained the patented process of M. René Cupper, of Paris, for extracting iodine from sea water, which consists in the use of a new precipitating liquid composed of sulphate of copper, sulphate of the protoxide of iron, tartaric acid, and tartrate of ammonia, of which a mixture of only three pounds and a quarter—and which are afterwards nearly all recovered—precipitate one pound of iodine in the state of iodotartrate of protoxide of copper from 25,000 lbs. of sea water at a cost of about $1·50 per pound. He stated the present yearly importation (none being manufactured in America) as 120,000 pounds, at a price varying between $5·50 and $6 per pound. M. Fleury also gave a description of the properties of sulphide of silicium, and its preparation by the action of sulphur and carbon on quartz, or flint. He explained the manufacture of a pure hydrate of silica, a neutral solution of flint or opal in water, resulting from the decomposition of the sulphide of silicium. M. Fleury remarked that gold quartz could cheaply be brought from Nova Scotia to Boston, converted into sulphide of silicium, dissolved in water, and all the gold precipitated by specific gravity and forcing of the suspended particles through mercury; that the liquid (the value of which would more than pay for the expense of extracting the gold) mixed with other cheap materials of a proper consistency can, when poured into moulds, without application of fire or any heat whatever, form excellent snow-white flint marble statuary, tombstones, ornaments, and building-stones, hard enough to resist all the influences of the weather better than natural marble. M. Fleury remarked further that the cost of this flint-marble statuary, &c., is less than one-third of that of cut or chiselled marble.—*Scientific American.*

On the Economical Preparation of Sulphate of Magnesia.—M. Mirns prepares sulphate of magnesia from the residues of the manufacture of carbonic acid from magnesite and sulphuric acid. Those residues containing iron and lead (from the sulphuric acid) are set aside. The residues ought not to be acid; thus it is convenient to work with an excess of magnesia. If there is iron, add a little lime; if there is lead, a little sulphide of calcium obtained by igniting plaster of Paris with carbon. Do not filter, but decant, after having sufficiently diluted it to avoid crystallisation; after which, evaporate till the thermometer shows a temperature of 104° C. The liquid now solidifies on cooling. Then run it into a wooden vessel, and agitate it from time to time, so as to obtain small crystals. The small amount of mother liquor is submitted to a new concentration.—*Arch. der Pharm.* cxxvii. p. 195.

ANSWERS TO CORRESPONDENTS.

*** All *Editorial Communications* are to be addressed to the Editor and *Advertisements* and *Business Communications* to the Publisher, at the Office, 1, Wine Office Court, Fleet Street, London, E.C. *Private* letters for the Editor must be so marked.

*** In publishing letters from our Correspondents we do not thereby adopt the views of the writers. Our intention to give both sides of a question will frequently oblige us to publish opinions with which we do not agree.

Vol. XIV. of the Chemical News, containing a copious Index, is now ready, price 11s. 0d., by post, 11s. 6d., handsomely bound in cloth, gold-lettered. The cases for binding may be obtained at our Office, price 1s. 6d. Subscribers may have their copies bound for 2s. 6d. if sent to our Office, or, if accompanied by a cloth case, for 1s. Vols. I., II., and VII. are out of print. All the others are kept in stock. Vol. XV. commenced January 4, and will be complete in 26 numbers.

G. L.—Received with thanks.

J. Knight.—The Millo Petroleum Gas-lamp is made by Messrs. Leplay and Noël, 14, Rue Belzance, Paris. A description of it was given in our number for January 11, page 16 of this volume.

M. J. S.—The topaz is destroyed by heat. Intense ignition drives off all the fluorine in the state of fluoride of silicium, and leaves silicate of alumina.

Student, R.C.C.—Yttria is contained in some specimens of cerite, but not in all. A friend of ours has worked up some hundredweights of cerite with the object (*inter alia*) of preparing the yttria from it, and did not find a trace.

Teroxide of Antimony.—A correspondent has seven or eight cwt. of teroxide of antimony, chemically pure, with the exception of a trace of free chlorine. He wishes to dispose of it, and will be glad to know what price can be offered for the whole or part of it.

Querist.—Palladium is very expensive and rare at the present time. If you have a stock of it, you need be in no want of a subject for original investigation. The remarkable behaviour of the solid metal towards gases is well worth all the attention you can bestow upon it. The organic compounds of palladium have also been very little studied.

Japhet Farquerson.—Bellini has given the best directions for treatment in cases of phosphorus poisoning. He relies upon the administration of ether to arrest the combustion of phosphorus in the stomach, and makes the patient inhale air containing a little ether vapour. This treatment he supplements with emetics and purgatives, and administers mucilaginous liquids and magnesia to neutralise the phosphoric acid. M. Barreswil, commenting on this, says that he prefers spirits of turpentine to ether. The chemical portion of this treatment is, no doubt, excellent. Whether it would answer in a medical point of view is more than we can say. Chemists, when they turn medical men, are too apt to consider the stomach as a test-tube, and expect chemical reactions to go on in it just as neatly as they do at a lecture table.

THE CHEMICAL SOCIETY.

In our report in another column of the anniversary meeting of this Society held on Saturday last, we give, as in duty bound, without comment, a simple report of the proceedings. We should, however, scarcely be doing our duty as faithful chroniclers of the proceedings of the Society were we to omit all reference to an under-current of excitement which has stirred the Fellows for some time past, and, but for the admirable tact and forbearance of its officers, would have culminated in serious injury to the Chemical Society.

It is known to many of our readers that the proceedings at the anniversary meeting are mostly of a formal character, no papers being read, and, possibly owing to this cause, it is, as a rule, very scantily attended. The principal business is to elect the officers and Council for the ensuing year, and, to facilitate this object, the laws provide that printed lists of those members whom the Council recommend for election should be previously sent to every Fellow of the Society, who, should he think that he can suggest any better representatives than those proposed by the Council, may substitute other names on his voting paper, and hand it to the scrutators whose duty it is to report which candidates have received the greatest number of votes. The chairman then announces the result to the meeting, and the election is complete. Effective provision is thus made for giving to each Fellow of the Society a free voice in the election of representatives, and members are of course perfectly justified in discreetly exercising this right whenever they think fit. In practice, however, in this, as in all other scientific societies where similar regulations exist, the members are satisfied with possessing this right, and seldom or never exercise it. But few instances are on record in which the list proposed by the Council of a learned society has not been accepted unanimously.

Most Fellows of the Chemical Society will hear with considerable surprise that the proposed list of officers and Council which they received a few weeks ago has met with an organised opposition. A young gentleman of little more than a year's standing in the Society, whose claims for distinction over any of the 500 other Fellows are absolutely *nil*, has had the presumption to set his own crude conception of what is best for the interests of the Society in opposition to the sagacity and matured experience of the Council. In total ignorance of the principles which guide the selection of Council and officers, our revolutionary young friend ventured to nominate another President, another Secretary, another Treasurer, and sundry other members of Council. This is sufficiently startling; but this is not all. He has not scrupled to go about soliciting votes to place upon the Council——himself! Need we stop to characterise conduct like this? However, the preposterous cabal signally failed. But for the proverbial impossibility of keeping a plot secret, he might, with the aid of a handful of supporters, in a scant general meeting, have snatched a short-lived triumph. As it happened, however, the friends of the Society mustered in force, and, by a majority of nearly four to one, decisively crushed the unwarrantable opposition.

Now, we do not wish to stop the reasonable exercise of the right of members to question the nominations of the Council. Indeed, we have noticed several cases in which that right might have been very advantageously enforced; but this reckless, unjustifiable, wholesale substitution of names passes the bounds of legitimate interference. We appeal to the good sense of the few who were misled on this occasion to compare the existing list with the counter-list which was rejected, and to ask themselves seriously whether it would have been an improvement. Where it is proposed simply to replace one eminent man by another equally eminent, no great harm would be done either way; but for the members to be asked to remove from the Council men who have grown grey in the service of science, whose words are listened to with attention, whose papers are read with interest wherever civilisation has penetrated, and to replace them, among others, by one who, beyond a very limited circle of young admirers, carries no weight whatever, is a proposition unfit for serious discussion.

For the future, care must be taken to prevent the Society becoming unawares, even temporarily, at the mercy of a small minority. In the present instance, if entrapped into a defeat in the meeting-room, by the efforts of a numerical majority, but constituting really an insignificant fraction of the Society at large, it is not improbable that the Council would have resigned in a body, and thus jeopardised the very existence of the Society.

An alteration in the customary method of voting would obviate such difficulties in future. All Fellows of the Society possess a voice in the election of their Council and officers, but at present this responsible duty is exercised only by the few London members who will take the trouble to attend these anniversary meetings. Cancel the rule which makes personal presentation of the voting papers necessary, and allow them, properly signed, to be sent up to the Secretary by post, or handed in by friends, and the difficulty would vanish. The elections then, instead of being liable to fall under the control of a small clique, would be carried out by the whole body of Fellows; and the governing body, in that case, would more truly represent the wishes of the Chemical Society of England than is possible under any system which necessitates personal voting.

Viennese Meerschaum.—The product known as Viennese meerschaum is prepared by mixing 100 parts of silicate of sodium at 35° with 60 parts of carbonate of magnesium and 80 parts of the native meerschaum or pure alumina. This mixture is then pulverised with the greatest care, and passed through a sieve of very fine silk or horsehair; add water, and boil it for ten minutes; then pour the whole into moulds, placed so that the water may separate easily.—*M. Holdmann.*

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On the Classification of Native Silicates, by* WILLIAM ODLING, *M.B., F.R.S.*

THE silicates of different metals constitute, both in number of species and extent of distribution, by far the most abundant class of native minerals. They are found in well-defined crystals, and in the crystalloidal, fibrous, and amorphous states, both as isolated compounds, and as variously mixed constituents of different rocks. Granite and gneiss, for example, consist chiefly of quartz or silica, felspar, and mica; syenite of quartz, felspar, and hornblende; porphyry and trachyte of felspar; and basalt of felspar with augite and labradore. Hornblende also occurs, intimately mixed with felspar or albite, in the form of greenstone; chlorite in different varieties of slate; and serpentine in serpentine rock.

The determination of the formulæ of many native silicates is a matter of considerable difficulty, on account more especially (α) of the several different classes of silicates which undoubtedly exist; (β) of the variable isomorphous replacement of different metals by one another in the same silicate; (γ) of the unknown function of fluorine, chlorine, boric oxide, and alumina in certain mixed silicates; (δ) of the unknown function of hydrogen on certain hydrated silicates; (ϵ) of the occurrence even in well-crystallised silicates of accidental impurities; (ζ) and, lastly, on account of the great complexity of many native silicates, and consequent unavoidable inaccuracy in their analysis.

(α) The great majority of native silicates, probably four-fifths of the entire number, are divisible into four principal classes, known as sesqui-, meta-, para-, and ortho-silicates, which may be represented respectively by the following general formulæ. A few anhydro-silicates, containing an excess of silica beyond that found in the sesqui-silicates, are also known; while in one or two aluminous silicates, the proportion of silica is less even than in the ortho-silicates—

Sesqui-silicates	$x(M_2Si_3O_8)$	or	$x(2MO.3SiO_2)$
Meta-silicates	$y(M\ Si\ O_3)$	,,	$y(\ MO.\ SiO_2)$
Ortho-silicates	$z(M_2Si\ O_4)$	,,	$z(2MO.\ SiO_2)$
Para-silicates	$z(M_2Si\ O_4)\ .\ y\ (MSiO_3)$		

The combinations of most frequent occurrence among members of the intermediate class of para-silicates are the three following, and especially the second of them, but others are occasionally met with—

$2M_2SiO_4.1MSiO_3$ or $5\ MO.3SiO_2$
$1M_2SiO_4.1MSiO_3$,, $4\frac{1}{2}MO.3SiO_2$ or $3MO.2SiO_2$
$1M_2SiO_4.2MSiO_3$,, $4\ MO.3SiO_2$

It is observable that the ratio of the oxygen of the base to the oxygen of the silica is as 1 to 1, or 2 to 2, in ortho-silicates; most generally as 3 to 4, but variable between 2 to 2, and 1 to 2 in para-silicates; as 1 to 2 in meta-silicates; and as 1 to 3 in anhydro-sesquisilicates. Accordingly it is found convenient in many cases, for the sake of comparison, to express the composition, more particularly of complex silicates, by formulæ which render these oxygen ratios most easily apparent, as in the following examples—

$\frac{1}{4}$ Ortho-silicate	$Ca_3Al_2O_6.Si_3O_6$	Garnet.
$\frac{3}{4}$ Para-silicate	$Ca_6Al_2O_9.Si_6O_{12}$	Humboltite.
$\frac{1}{2}$ Meta-silicate	$K_2\ Al_2O_4.Si_4O_8$	Leucite.
$\frac{1}{3}$ Sesqui-silicate	$K_2\ Al_2O_4.Si_6O_{12}$	Felspar.

* Dr. Odling has kindly given us permission to publish occasional chapters from the forthcoming second part of his "Manual of Chemistry."—ED. C. N.

(β) Although many native silicates exhibit a tolerable constancy of composition, other well-defined species are observed to enjoy a wide range of variation, through the isomorphous substitution in them of one constituent for another. Thus, the monad alkali-metals lithium, sodium, and potassium—occasionally all three, very frequently any two of them—are found replacing each other in all proportions; while among diad metals, magnesium and calcium seldom occur in the form of silicates, as entirely separate compounds, and, in the same mineral species, are met with in every variety of isomorphous admixture. Both—but more especially calcium—are in certain silicates replaceable to a greater or less extent by alkali-metal; while both—but more especially magnesium—are, in most silicates, habitually replaced by some iron and manganese, in the diad forms of ferrosum and manganosum. In many aluminous silicates, again, a portion of the triad or pseudo-triad aluminium is replaced by iron, with or without some chrome and manganese, in the forms of ferricum, chromicum, and manganicum.

In writing the formulæ of silicates, complex by reason of the greater or less mutual substitution of isomorphous metals in them, it is customary to express only their leading constituents. Thus, a variety of uniaxial mica is expressible as a parasilicate by the formula $Mg_2Al_2O_3.Si_3O_6$, or $Mg_2Al_2Si_3O_{11}$. But in reality a variable proportion of the magnesium is found to be replaced by iron, manganese, calcium, and potassium, and a variable proportion of the aluminium by ferricum, so that the full formula of the mineral would be—

$$(Mg\text{-}Fe\text{-}Mn\text{-}Ca\text{-}K)''_2\,(Al\text{-}Ffe)'''_2\,O_5\,.\,Si_3O_6.$$

Moreover, although in many complex silicates the ratio of diad to triad metal is most constant and characteristic, as in the garnets, it seems to be established beyond all question, that in other and even closely allied species, as the idocrases, the ratio is very variable, ferrosum and the diads generally replacing ferricum and the triads isomorphously, in the proportion of $_3FeO$ to $FfeO_3$.

The well-defined mineral epidote, for instance, is usually formulated thus—$Ca_3Al_4O_9.Si_4O_8$, or, more fully, thus—

$$(Ca\text{-}Mg\text{-}Fe\text{-}Mn)''_3\,(Al\text{-}Ffe\text{-}Mm)'''_4\,O_9\,.\,Si_4O_8.$$

But Laurent showed, by an examination of the actual analyses of fifteen different varieties of epidote from different localities, that the average experimental ratio of the oxygen of the bases to the oxygen of the silica was as 99·7 to 100, and the extreme range of ratio between 95·5 to 100, and 103 to 100. On the other hand, the ratio of the oxygen of the triad bases to the oxygen of the silica ranged between 69 and 51 to 100, with a mean of 64·2 to 100, while the ratio of the oxygen of the diad bases to the oxygen of the silica ranged between 30·2 and 45·8 to 100, with a mean of 35·5 to 100. Epidote, accordingly, proves to be a complex ortho-silicate, expressible by the formula $(Ca\text{-}Al)O_2.SiO_2$, or $(Ca\text{-}Al)SiO_4$.† In the micas, again, while the ratio of the oxygen of the united bases to the oxygen of the silica varies only between $\frac{11}{12}$ths and $\frac{12}{12}$ths, the ratio of the oxygen of the joint monad and diad bases to the oxygen of the triad bases varies between $\frac{1}{0}$th and $\frac{1}{0}$ths in different specimens. By having regard to this partial mutual replacement of diads and triads, many other silicates, usually expressed by very complex formulæ and oxygen ratios, are reducible to some one or other comparatively simple type.

† The mean result of all the analyses is represented by the formula $Ca_5Al_6O_{14}.Si_7O_{14}$.

(γ) Fluorine, replaceable wholly or partly in certain minerals by chlorine, is met with as a constituent of several native phosphates, silicates, borates, and aluminates. It would seem that in some cases the halogen acts simply as a salt-radical, supplying the place of a deficiency of oxygenised radical. Thus, in wagnerite, two atoms of diad magnesium are associated with one atom of triad oxiphosphion, and with one atom of monad fluorine, to form a double salt of the ordinary character, expressible by the formula $Mg''_2|PO_4)'''F$.‡ Again, in apatite $Ca''_5|PO_4)'''_3F$, and polymorphite $Pb''_5|PO_4)'''_3F$, the halogen would seem to fulfil a similar function in balancing the excess of base-equivalent, although it has not escaped notice that in apatite, at any rate, the amount of halogen is liable to much variation, becoming in some specimens almost infinitesimal.

But it is well known that the halogens, more especially fluorine, can form saline compounds, differing only from ordinary salts in the substitution of fluorine for oxygen. Thus we have the fluoboride KBF_4, corresponding to borate of potassium KBO_2; fluosilicide of calcium $CaSiF_6$, corresponding to wollastonite $CaSiO_3$, &c. Now it would appear that, in most halogenous silicates and borates, the constituent halogen does not compensate for an atomic deficiency of oxygenised radical, but replaces an indefinite proportion of oxygen in the radical isomorphously. This is well seen in boracite, some specimens of which are quite free from halogen, and referrible to the formula MgB_2O_4. But in many boracites, about $\frac{1}{16}$th part of the oxygen is substituted by chlorine, so that the formula has to be written $MgB_2(OCl)''_4$, or more fully $Mg_4B_8(O_{15}Cl_2)$.§ Again, in topaz, Al_2SiO_5, a quantity of the oxygen varying from $\frac{1}{8}$th to $\frac{1}{6}$th part is found to be replaced by fluorine, so that the formula of the compound has to be written $Al_2Si(OF)''_5$, or more fully, though not so accurately, $Al_6Si_3(O_{13}F_4)$. It is noticeable that neither in boracite nor topaz does the halogen replace an entire proportion of oxygen, in what may be considered as a unit of the mineral; while in most other halogenous minerals, as in the micas, hornblendes, and tourmalines, the replacement is still more limited and irregular. The determination of the function fulfilled by fluorine or chlorine in any particular silicate is a question for the judgment, but in those cases where it is believed to replace an indefinite quantity of oxygen isomorphously, its expression may be omitted from the usual formula of the silicate, just as the expression of the secondary metals, substituted isomorphously to a greater or less extent for the principal metals of other silicates, is omitted from their respective formulæ.

(To be continued.)

On the Application of the Blowpipe to the Quantitative Determination or Assay of certain Metals, by David Forbes, *F.R.S., &c.**

(*Continued from page* 40.)

Silver Assay.—The blowpipe assay of silver ores was first described in 1827 by Harkort,† and subsequently considerably improved by Plattner. This assay process is in all cases based upon the reduction to a metallic state of all the silver contained in the compound in question along with more or less metallic lead, which latter metal, when not already present in sufficient quantity in the substance itself under examination, is added in the state of granulated lead to the assay previous to its reduction. The globule of silver-lead thus obtained, if soft and free from such elements as would interfere with its treatment upon the cupel, may then be at once cupelled before the blowpipe until the pure silver alone remains upon the bone-ash surface of the cupel; but if not, it is previously submitted to a scorifying or oxidating treatment upon charcoal until all such substances are either slagged off or volatilised, and the resulting silver-lead globule cupelled as before.

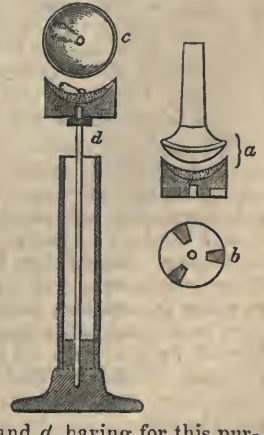
As, therefore, the final operation in all silver assays is invariably that of cupelling the silver-lead alloy obtained from the previous reduction of the substance, effected by methods differing according to the nature of the argentiferous ore or compound under examination, it is here considered advisable to introduce the description of the silver assay by an explanation of this process.

In the ordinary process of cupellation in the muffle, bone ash or other cupels are employed of a size large enough to absorb the whole of the litharge produced from the oxidation of the lead in the assay.

This, however, should not be the case when using the blowpipe; for as the heating powers of that instrument are limited, it is found in practice much better to accomplish this result by two distinct operations—the first being a concentration of the silver-lead in which the greater part of the lead is converted by oxidation into litharge remaining upon, but not, or only very slightly, absorbed by, the bone-ash cupel; and the second in cupelling the small concentrated metallic bead so obtained upon a fresh cupel until the remaining lead is totally absorbed by the cupel and the silver left behind in a pure state. By this means a much larger weight of the silver-lead alloy can be submitted to assay, and, for reasons hereafter to be explained, much more exact results are obtained than would be the case when the cupellation is conducted at one operation in the ordinary manner.

The apparatus used by the author for these operations are shown to a scale of one-half their real size in the woodcuts Fig. 5 (*a* to *d*).

Fig. 5.



In Fig. 5 *a* is represented in section a small cylindrical mould of iron, seven-tenths of an inch in diameter, and about four-tenths high, in which is turned a cup-shaped nearly hemispherical depression two-tenths of an inch deep in centre, the inner surface of which is left rough, or marked with minute ridges and furrows for the purpose of enabling it to retain more firmly the bone-ash lining, which is stamped into it by means of the polished bolt also shown in the figure. This mould rests upon the stand *d*, having for this purpose a small central socket in its base, into which the central pivot of the stand enters. This socket is seen in the ground plan *b* of the base of the mould, which shows likewise three small grooves or slots made in same to enable a steady hold to be taken of it, when hot, by the forceps. The stand itself is composed of a small turned ivory or wood base, fixed into a short piece of

‡ In such expressions as this, the reader will recognise an adoption of Mr. Graham's antithetic formulæ.

§ Usually written $3MgO.4B_2O_3.MgCl_2$.

* Communicated by the author.

† *Die Probirkunst mit dem Lothröhre*, Freiberg, 1827, I. Heft (all published).

strong glass tubing, which, from its non-conducting powers, serves as an excellent handle. In centre of the base a slight iron rod rising above the level of the glass outer tube serves as a support for the cupel mould, into the socket in the base of which it enters.

Bone ash is best prepared by burning bones which previously had been boiled several times, so as to extract all animal matter. The best bone ash is made from the core-bone of the horns of cattle well boiled out and burned. The ash from this is more uniform than from the other bones, which have in general a very compact enamel-like exterior surface, whilst the interior is of a much softer nature.

Concentration of the Silver-lead. — A cupel is prepared by filling the above-described cupel mould with bone-ash powder not finer than will pass through a sieve containing from forty to fifty holes in the linear inch, and should be well dried and kept in an airtight bottle, and the whole pressed down with the bolt, using a few taps of the hammer. It is then heated strongly in the oxidating blowpipe flame in order to drive off any hygroscopic moisture. The bone-ash surface of the cupel, after heating, should be smooth, and present no cracks; if the reverse, these may be removed by using the bolt again and reheating.‡ The silver-lead, beaten on the anvil into the form of a cube, is placed gently upon the surface of the bone ash, and, directing a pretty strong oxidating flame on to its surface, it is fused, and quickly attains a bright metallic appearance, and commences to oxidise with a rapid rotatory movement. (Occasionally, when the assay is large, and much copper or nickel present, the globule may, under this operation, cover itself with a crust of oxide of lead or solidify; in such cases direct the blue point of a strong flame steadily on to one spot on the surface of the lead globule until it commences oxidating and rotating. In some cases where much nickel is present, an infusible scale, impeding or even preventing this action, may form, but will disappear on adding more lead—say from three to six grains, according to the thickness of this scale or crust.) When this occurs the cupel is slightly inclined from the lamp, and a fine blue point obtained by placing the blowpipe nozzle deeper into the flame, and the lamp is directed at about an angle of 30° on to the globule—not, however, so near as to touch it with the blue point, but only with the outer flame, so moderating it as to keep the assay at a gentle red heat, and not allowing the rotation to become too violent.

This oxidating fusion should be carried on at the lowest temperature sufficient to keep up the rotatory movement, and to prevent a crust of litharge accumulating upon the surface of the globule, but still sufficiently high to hinder the metallic globule from solidifying. Should this, however, happen, a stronger flame must be employed for a moment until the metal is again in rotation; such interruptions should, however, be avoided. The proper temperature can only be learned by practice, a too high temperature is still more injurious, causing the lead to volatilise, and, if rich in silver, carry some of that metal mechanically along with it. The litharge also, instead of remaining on the cupel would be absorbed by the bone ash, and as the surface of the metallic globule is covered by a too thin coating of fused litharge, some silver may be absorbed along with the litharge. In this operation, in order to avoid loss of silver, the fused globule should be always kept in contact with the melted litharge.

By the above treatment, the air has free access to the assay, and the oxidation of the lead and associated foreign metals goes on rapidly. The surface of the melted globule, when poor in silver, shows a brilliant play of iridescent colours, which does not take place when very rich in silver. The litharge is driven to the edge of the globule, heaping itself up and solidifying behind and around it. When the globule becomes so hemmed in by the litharge as to present too small a surface for oxidation, the cupel is moved so as to be more horizontal (having been previously kept on an inclined position), thus causing the lead globule to slide by its own weight on one side, and expose a fresh surface to the oxidising action. When the lead is pure, the litharge formed has a reddish-yellow colour, but, if copper is present, is nearly black.

In concentrating silver-lead, it must be remembered that an alloy of lead and silver, if in the proportion of about 86 per cent. silver along with 14 per cent. lead, when cooled slowly in the litharge behaves in a manner analogous to the spitting of pure silver, throwing out a whitish-grey pulverulent excrescence rich in silver. For this reason, therefore, the concentration above described should be stopped when the globule is supposed to contain about six parts silver along with one part in weight of lead. In case, however, this limit should have been exceeded, it is advisable at once to push the concentration still further until the silver globule contains but very little lead. In practice with poor ores it is usual to concentrate the lead until the globule is reduced to the size of a small mustard seed, or in rich ores to some two or three times that size. Upon arriving at this point, the cupel is withdrawn very gradually from the flame, so that the cooling shall take place as slowly as possible until the globule has solidified in its envelope of litharge. If cooled too quickly, the litharge, contracting suddenly, would throw out the globule, or even cause it to spirt; in such case it should be touched by the point of the blue flame so as to fuse it to a round globule, which is cooled slowly, as before described. The globule is now reserved for the next operation, for which purpose it is, when quite cold, extracted from the litharge surrounding it.

(To be continued.)

‡ These precautions are very important, as the slightest trace of moisture in the substance of the bone ash would inevitably cause a spirting of the metal during the operation.

Analytical Notes on Cadmium, by Professor F. WÖHLER.

Separation of Cadmium from Zinc.—Add a considerable excess of tartaric acid to the solution containing these two metals. Then add solution of caustic soda until the reaction is decidedly alkaline, and after dilution with much water keep the solution in a state of ebullition for several hours. Only the cadmium is deposited. The zinc may be separated from the filtrate by sulphide of ammonium.

Separation of Cadmium from Copper.—Well wash the precipitated sulphides, and then dissolve them in hydrochloric acid, to which is added chlorate of potash. Precipitate the solution by an excess of potash, and dissolve the precipitate in hydrocyanic acid. This will form a solution of double cyanides, from which sulphuretted hydrogen precipitates the cadmium, but not the copper. Or the solution of the sulphides may be treated as in the case of cadmium and zinc, and the filtrate containing the copper oxidised with aqua regia and precipitated with caustic potash.

Copper and cadmium may also be separated by precipitating the former with sulphocyanide of potassium, after having first reduced it with sulphurous acid.

PHARMACY, TOXICOLOGY, &c.

The New Pharmacopœia (1867).

In a few weeks — we hope in time for the summer course at the various medical schools—will be published a work which, the *British Medical Journal* says, will be one of the best Pharmacopœias extant, yielding to none of the foreign ones. It will, of course, by the criticism that it meets with abroad, reflect indirectly upon the present state of the higher science of chemistry in England, and so we propose to give our readers an outline of the changes that have been made since the publication of the first national Pharmacopœia.

The book itself will be cheaper than the last edition was; we believe the price will be 6s., and a very large number of copies will be prepared, as it is expected that another edition will not be required for some time.

The preparation of the work has been attended with little cost when compared with the first British Pharmacopœia; and it is expected that, commercially, the result will be a gain to the Medical Council instead of a loss, as before.

The general arrangement of matter will make reference very easy. All the substances follow the alphabetical order of the Latin names, so the book looks like a dictionary. An index is given supplementary to this, so that if the Latin name be not known or forgotten the information is supplied by a reference to the English names and synonyms. This, our readers will at once see, is a radical change from the arrangement of the current edition, and it certainly gives a much more pleasing and concise appearance to the whole.

An addition of still greater value is a list of all the preparations in which the drug under discussion is contained, with the proportion shortly stated. This information previously was only to be obtained from the indices of Materia Medica manuals, or companions, &c., to the Pharmacopœia. In this way most of such handbooks will become superfluous.

Another encroachment upon what has before now been considered the special province of this class of books is the addition of the doses, "the quantities stated under this head being intended to represent average doses in ordinary cases for adults. The doses are not authoritatively enjoined by the Council, and the practitioner must rely on his own judgment and act upon his own responsibility in graduating the doses of any therapeutic agents which he may wish to administer to his patients."

This will be matter of self-congratulation to the student, who up to this date has had of course to work up the doses given by the examiner in a text-book or otherwise, as it is well known that opinions differ much on the point.

There are ninety-nine substances in this new edition not to be found in the previous one; these consist of things new and old, new drugs recommended by the party of progress, and pet remedies of men of the old school contained in the Pharmacopœias of the different colleges of the United Kingdom.

This, therefore, like so many other successful English institutions, is a compromise, and, indeed, a liberal spirit is required in this respect in the present state of medical science, however clear it may be that the tendency of scientific pharmacy and medicine is to a decrease, not an increase, in the number of remedies.

For example, if chemists show that oak-bark, elm-bark, catechu, &c., all and each derive their virtues from tannin, it would be thought that a mere statement of the fact would make some dozen drugs of this description at once obsolete. Further, when tannin is shown to be a glucoside, which glucoside breaks up in the human body into dextrine and gallic acid, the gallic acid being found as such in the urine, gallic acid would be supposed to supersede at once the use of tannin.

We are sorry that this rational progress should be interfered with by such an increase in the number of drugs. The Pharmacopœia does not sin so much by commission in this respect as by omission; when new substances are introduced at such a rate, room should be made for them in the manner we have indicated. Four substances found in the last edition are omitted in this new one—black catechu, cocculus, ointment of cocculus, rectified pyroxylic spirit.

They may be very well spared, and we hope that, now that the protecting wing of medicine is taken from the cocculus indicus, no excuse will remain for its importation, and its finally finding its way into beer to such a large and deleterious extent.

Two new classes of substances are now introduced for the first time, inhalations (prussic acid, chlorine, conia, creosote, iodine); glycerines (carbolic acid, gallic acid, tannic acid, starch, borax); while the essences are restored from the Dublin (anise and peppermint), and the vinegars (Spanish fly and squills) from the London Pharmacopœias respectively, omitted in the first British Pharmacopœia.

FOREIGN SCIENCE.

(From our own Correspondent.)

Paris, April 3, 1867.

One of the greatest curiosities of the Universal Exposition, opened on Monday last, is the laboratory of the Imperial Commission, constructed quite near the entrance at the side of the Pont d'Jena. It is under the special direction of M. Grandeau, one of the organisers of Class 44 (*Produits Chimiques et Pharmaceutiques*), with the collaboration of MM. Sainte-Claire Deville, Debray, Troost, Captain Caron, Schloessing, &c. A portable gasometer, after the system of M. Jouanne, gives oxygen gas furnished by the apparatus of M. Tessié de Mothay for the Drummond or Carlevaris lamp, or for the oxyhydrogen lamp of M. Schloessing, of which M. Wiesnegg, No. 5, Place de la Sorbonne, makes at present excellent models. The Imperial Commission has decided that the laboratory shall be placed at the disposition of all the metallurgical chemists, &c., who may require to make experiments or assays. It is from this laboratory that will be procured for our lecture-hall the oxygen gas which is to serve for the supply of the magnesia lamp.

Mr. Sterry Hunt, who is at this moment in Paris, where he represents Canada at the Universal Exhibition of 1867, has informed us of a considerable progress that has taken place recently at Boston, U.S., in the heating of steam generators. In this new and curious method the coal is reduced to a very fine dust, and is blown or injected by a current of compressed air into the furnace, where it burns with a very intense flame. By this means nothing is lost, and the production of steam is much greater. It is astonishing that no one has thought of making use in this way of the immense quantities of coal-dust which are now annually wasted at the pit's mouth.

We return to the subject of the production of oxygen gas by the decomposition of sulphuric acid; and this reminds us principally that, in itself, and independently of

the essential perfections that it can receive, the process has come before the public in the form in which it had been applied formerly by MM. Peligot and H. Sainte-Claire Deville. One of these essential improvements, discovered and patented by M. Tessié de Mothay, consists of—1, decomposing sulphuric acid by making it fall, at a temperature of more than 1500° C., upon a thick layer of sulphate of alumina, which is decomposed at nearly the same temperature, and protects at the same time the metallic vessel in which the decomposition is effected; 2, to conduct the mixture of oxygen and sulphurous acid thus disengaged through carboys containing magnesia at the most favourable temperature for its combination with the sulphurous acid separated; or else by forming sulphite of soda, in which operation it is absorbed in such a manner that it can be despatched to any distance, and can serve, instead of pyrites, for the disengagement of sulphurous acid ready to be converted into sulphuric acid in the leaden chambers. The process thus put in practice of the preparation of oxygen by sulphuric acid, although theoretically inferior to that by the manganate of soda, becomes truly a branch of industrial art, and can be applied in various ways.

M. Z. Roussin has called our attention to a barefaced fraud practised for some time past on soaps with potash bases, called soft soaps, black soaps, green soaps, which are employed daily in the pharmaceutical and veterinary arts, and for domestic purposes. Out of sixteen samples of soft soaps procured at hazard at different shops in Paris, M. Roussin found 10, 20, and often 25 per cent. of fecula of inferior quality, not to be detected by simple inspection. The difference of price between the feculæ of bad quality and the soft soaps sufficiently explains the motive for this adulteration. The feculæ, in fact, are sold at 20 to 45 fr. the 100 kilogrammes, while the price of pure soft soaps is from 60 to 70 fr. In order to ascertain the presence of the fecula, all that is necessary is to press between the two glass discs of a microscope a little soft soap about the size of the head of a pin. Hundreds of amylaceous granules appear under the magnifying power, most of them being swollen. If it is required to know the proportion of fecula mixed with the soap, take 10 grammes of soap, and dissolve it cold in 30 or 40 cubic centimetres (3 or 4 centilitres) of alcohol of 85 per cent. The pure soap is dissolved, and the fecula is deposited. This, when dried, is in the state of a pulverulent mass, of a grey colour, that can be weighed, and which, boiled with water and brought into the state of starch, colours enormous quantities of water when a solution of iodine is added.

On the subject of the nodules possessed by the Comte de Douchet, which have the same composition as anthracite and the hardness of the diamond, and even greater, since they are able to scratch the latter, M. Charles Mène reminds us of the experiments he made upon an anthracite coal from Creuzet, the composition of which is—carbon 0·982, hydrogen 0·002, oxygen 0·004, ash 0·012. Heated to a high temperature and for a long time in a crucible in the middle of a coke furnace, this black diamond takes a metallic lustre, of a remarkable character, in pieces which have the sp gr. 1·637, and which scratch and cut the hardest glass. Since the presentation of these nodules to the Academy of Sciences, M. de Douchet has been informed by an English gentleman that he had seen similar specimens in Australia. We shall examine the products of that wealthy and industrial English colony, as shown in our Exhibition, and acquaint our readers with the result.

Cement.—Alum and plaster of Paris well mixed together with water, and used in the liquid state, will form a very useful cement. It will be found handy in the laboratory for many purposes. It forms a very hard composition, and for fixing the brasses, &c., on paraffin lamps nothing could be better.

THE INAUGURATION OF THE PARIS EXHIBITION OF 1867.

(FROM OUR SPECIAL CORRESPONDENT.)

THE ceremony of the opening on Monday last was attended with the greatest success as regards weather and the punctuality of the imperial and royal personages, the officers of the commission, &c. Favoured by a brilliant sunshine, it took place in the presence of 100,000 persons in the building and park; the heights of Trocaders were also crowded with spectators.

The galleries of the Exhibition, for it can no longer be called a palace, do not present the wonderful and magic effect of the naves of the Crystal Palace at Hyde Park in 1851, and which now crowns the Sydenham hills; neither do they in any way resemble the Palais de l'Industrie in the Champs Elysées, and its annexes at the river side, which displayed a considerable area, yet deficient in *ensemble* and purpose; nor have they the shapeless and almost ridiculous outward form of the 1862 building at Kensington, redeemed, however, by the incontestably excellent interior arrangement. The galleries of 1867 present a new and original feature, and can be compared to no other building of the same nature; their appearance is monumental enough and worthy of containing the great industrial riches placed within its walls, and the arrangement described below is well adapted to their noble destination. The exterior has the form of an immense elliptical circus 490 metres long by 380 wide. It encloses 10 concentric galleries, ranged round a central garden containing about an acre and a quarter. These galleries are traversed by radiating alleys, of which those from north to south and from east to west form wide and extensive promenades. Each of the galleries is filled with products of a certain class. Thus we have—1. Works of art; 2. Materials and application of the liberal arts; 3. Furniture and other household objects; 4. Clothing and other personal objects; 5. Raw produce of manufacturing industries; 6. Apparatus and processes of the common arts; 7. Food, natural and preserved, and the processes of preparation; 8. Living products and specimens of horticulture.

The mode of distribution and of attribution of the circular galleries is very simple and ingenious. The outer circle (*machinery*) is 25 metres high by 35 wide, and is furnished with a broad middle platform about 20 ft. from the ground, from which all the machinery can be seen admirably. The building is to be ventilated by the system of M. Mondesir and Perigault's double fan, giving 700,000 cubic metres of air per hour.

The general masonry of the galleries and their foundations absorbed 50,000 cubic metres of materials; the framing used 13,500 tons of cast and wrought iron, and 53,000 square metres of thin boards for zinc roofing. It is almost incredible that this vast establishment was erected in about a year. M. Krantz, the now—and for ever—celebrated contractor of the Imperial Commission, was obliged, for the whole of this time, to design during the night what was to be built the following day. It is much to be regretted that heaps of irregular constructions, &c., completely hide the Exhibition building viewed from the Pont d'Jena, opposite the principal entrance; the buildings, also, for the hydraulic machines contribute not a little to this lamentable effect.

The ministers, the diplomatic corps, the members of the Household of their Imperial Majesties and Highnesses, the leading members of the Senate, the Legislative Assembly, and the Council of State took their places in the French gallery of the works of art; the persons invited by the Imperial Commission, the foreign commissioners, and the representatives of the Paris press filled the saloon of the exotic works of art. Our entrance card of invitation led us to the saloon No. 1 (paintings, sculp-

ture, and engraving of the States of the Church). At the entrance is a statue, nearly of full size, of Napoleon I., due to the chisel of the Milanese artist Vicenzo Valla, and bearing the following mournful inscription:—"*The last days of Napoleon the First:* depicted on the features are desolation and grief painfully startling."

While waiting for the *cortége*, we had an opportunity of admiring the meteorograph of the R. M. Secchi, Director of the Roman College Observatory, the principal scientific instrument in the building. This apparatus is unique of its kind in the whole world; wonderfully combined by the illustrious Professor, well constructed by M. Brassart, a Roman artist, worked by an electric clock made by M. Detouche, it enregisters, perpetually and automatically, day and night, the indications of all the instruments with which it is in communication, such as the barometer, thermometer, psychrometer, anemometer. Thus the observer finds it records every morning, week, or month faithfully and continuously inscribed. During our inspection of this instrument, the Baron de Havelt, Pontifical Commissioner, took this learned Jesuit away to present him to His Majesty the Emperor. Let us remark, also, the very remarkable works of art arrived from Rome: the painting of the Gate of Milan, by Mancinelli; the Prodigal Son, by M. Possy; three mosaics of middling dimensions, yet of incomparable beauty, by artists of the Vatican, and representing a head of St. Peter, the Virgin in the Chair by Raphael, the Virgin and the Infant Jesus by Sasso Ferrata; a piece of sculpture representing a man and woman endeavouring, by climbing a rock, to escape the waters of the Deluge; another representing a little boy giving to a young girl his dove, and many others too numerous to mention. The sculptures of M. Lucardi and the Contessa de Colonna (exhibiting under the name of Marcello) also expose some fine works, which received marked attention from their Majesties during their passage.

The Emperor and Empress left the Tuileries at 1.45 p.m., and arrived at the principal entrance of the Exhibition at 2 p.m. exactly. They were received, on alighting, by the Princess Mathilde, the Prince of Orange, the Count of Flanders, the Duc de Leichtenberg, and the Prince and Princess Murat.

At the door of the great vestibule they were received by the Imperial Commissioners and the Ministers, the Prefect of the Seine, Marshals, &c., and, preceded by the Commission, formed a *cortége*, which visited the building, after which it was open to the public. The entrance price for the day was 20 francs; it is to be 5 francs till Monday, April 8.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Saturday, March 30.

Professor W. A. Miller, M.D., V.P.R.S., *President, in the Chair.*

At this the anniversary meeting of the Society there was an unusually large attendance of Fellows.

The President read a report of the proceedings of the past year, from which it appeared that the finances and general condition of the Society were in a very flourishing condition. The present number of Fellows was 499, against 482 last year, and three foreign members had been added to the list, making in all 40, which is the full complement. It had been found necessary to remove, according to the Society's fourth by-law, and for non-payment of subscription, fourteen members; seven others have resigned, and the list of deceased Fellows included as many as eleven. These were Dr. James Allan, Mr. James Barrett, Mr. Thomas De la Rue, Mr. E. A. Hadow, Mr. W. M. Hindmarch, Q.C., Mr. Fearnside Hudson, Mr. Simeon Stoikowitsch, Mr. Edward Swann, Mr. John Mercer, F.R.S., Mr. Percival Johnson, F.R.S., F.G.S., and Major James Whitmore. Obituary notices of nearly all the deceased members were read. During the past year no less than fifty-four papers had been communicated to the Society, and four special lectures delivered by Prof. G. Carey Foster, Mr. Vernon Harcourt, Dr Debus, and Dr. Matthiessen respectively. 100*l.* had been voted for the purchase of books on the library account, and the Council had now under consideration a proposal for raising the standard of qualification for Fellowship.

The Treasurer then presented his financial statement, which had been certified by the auditors and showed a balance at the bankers' of 802*l.*, besides an increased investment, now amounting altogether to 1800*l.* Government Consols. The receipts of the Society amounted to 1848*l.* 16s. 1d., including the last year's balance of 762*l.* 8s. 11d. The expenses amounted to 1046*l.* 12s. 5d., including purchase money of 500*l.* Three per Cent. Consols. The outstanding subscriptions were estimated at 250*l.*

The election of officers for the year ensuing was then proceeded with, Messrs. E. C. Nicholson and Alfred Smee being appointed scrutators. The result of the ballot was declared to be exactly in accordance with the printed programme of changes proposed by the Council, and the following officers were duly elected:—For President Warren De la Rue, Ph.D., F.R.S. Vice-Presidents (who have filled the office of President): Sir B. C. Brodie, F.R.S., C. G. B. Daubeny, M.D., F.R.S., Thomas Graham, F.R.S., A. W. Hofmann, LL.D., F.R.S., W. A. Miller, M.D., F.R.S., Lyon Playfair, Ph.D., C.B., F.R.S., A. W. Williamson, Ph.D., F.R.S., Colonel Philip Yorke, F.R.S. Vice-Presidents: F. A. Abel, F.R.S., Walter Crum, F.R.S., J. H. Gladstone, Ph.D., F.R.S., John Stenhouse, LL.D., F.R.S. Secretaries: William Odling, M.B., F.R.S., A. Vernon Harcourt, M.A. Foreign Secretary: E. Frankland, Ph.D., F.R.S. Treasurer: Theophilus Redwood, Ph.D. Other Members of Council: F. Crace Calvert, F.R.S., J. Lothian Bell, Dugald Campbell, W. Crookes, F.R.S., F. Field, F.R.S., David Forbes, F.R.S., G. C. Foster, A. Matthiessen, Ph.D., F.R.S., H. M. Noad, Ph.D., F.R.S., W. J. Russell, Ph.D., Maxwell Simpson, Ph.D., F.R.S., J. A. Wanklyn.

A vote of thanks to the President for his services in the chair during the past year was moved by Mr. Alfred Smee, seconded by Mr. C. Greville Williams, and carried unanimously.

The retiring President, who was warmly applauded, acknowledged the support he had uniformly received both from his brother officers in the Council and the members attending the meetings. Dr. Miller briefly referred to the circumstance of his having been a fellow-student with Mr. Smee at King's College thirty years ago.

Professor J. A. Wanklyn proposed, and Mr. J. Newlands seconded, a vote of thanks to the other retiring officers, and also to the treasurer and secretaries, for their services during the year.

Dr. Odling spoke in acknowledgment, and briefly explained the principles upon which the Council proceeded to draw up the list of officers proposed for election. There were usually five retiring members—viz., one vice-president, and four ordinary members of Council. This year Dr. Stenhouse, the *senior* vice-president, remains, because Dr. De la Rue leaves that office to become president. Of the four members of Council two will retire by seniority, and two by least attendances. According to

this arrangement Dr. Hugo Müller and Dr. Debus (one *town* and the other *country* member) have necessarily gone out, whilst Dr. Letheby and Mr. Hadow (deceased) have given the other two places. Five vacancies thus created have been filled as follows:—Dr. J. H. Gladstone has become a vice-president, and Dr. A. Matthiessen an ordinary member of Council; there were besides three newly-elected members who have never served before—one from Newcastle, Mr. J. Lothian Bell, had a claim from the fact of his having stimulated the production of sodium and aluminium, besides according a magnificent reception to the chemists during the visit of the British Association. Mr. David Forbes was eminent as a mineralogical chemist, and would doubtless have been elected into the Council before but for the circumstance of his having been so long away from this country. And, finally, Professor J. A. Wanklyn was a good representative of pure chemistry, and an industrious worker in the science.

Other votes of thanks were passed in favour of Mr. H. Watts, librarian and editor of the journal, and also to the scrutators for their aid on this occasion. The meeting was then adjourned until April 4.

ROYAL INSTITUTION OF GREAT BRITAIN.

Friday, March 29, 1867.

Professor Frankland "*On the Water Supply of the Metropolis.*" Professor Frankland gave a long and interesting lecture on the above on Friday last, commencing with the subject of cholera epidemics. The lecturer spoke of the influence of the water supply both on the amount and the severity of the disease. He illustrated the first by the extent of the disease in Manchester, supplied by the springs of Derbyshire, and the second by the comparison of the mortalities of the former epidemics, when the Thames water was taken below Battersea Bridge, as compared with that of last year, when all the Thames water used by the metropolitan companies was taken from the river at Teddington Lock. A very different effect resulted from the use of the water from the Old Ford reservoir of the East London Company. The influence of this water upon the mortality of the immediate district being suspected by the Registrar-General, an examination had been proposed to the lecturer, who had demonstrated that, by infiltration of the soil by impure matter, the water must have been affected. This was amply confirmed when the reservoir was emptied by pumping. Nine companies now supply to the metropolis 108,000,000 gallons of water daily, but little idea of the vast volume of water is given by mere figures. Its storage would require a reservoir of the size of Westminster Hall, with its walls raised to a height of 1070 feet—more than three times as high as the Victoria Tower. Five of these companies took about half of the whole supply from above Teddington Lock, two of them (East London and New River) used the Lea, while the Kent and South Essex obtained theirs from artesian wells and springs. The metropolitan daily supply is at present 30 gallons per head.

There are five different schemes that have at present been proposed for a better supply:—1st. That of Mr. Bateman, from the sources of the Severn. 2nd. That of Messrs. Hemans and Hassard, from the lakes of Cumberland and Westmoreland. 3rd. That of Mr. Telford Macneil, from the district of the Bagshot sands, with a natural filtration through the sands. By the 4th scheme, from the sources of the Thames, by large reservoirs, with a larger supply than at present. The 5th from the hills of Derbyshire and Stafford, from the slope opposite that by which Manchester is at present supplied.

Of the last three schemes the lecturer said that too little was known of their details for them to be discussed. The quality of the water was not known to him, and the lecturer wished to confine himself to the chemistry of the water, and leave out of question the engineering details.

Mr. Bateman's supply was from the sources of the Severn. From the moisture of the Atlantic and the height of the surrounding hills, the rainfall here is very great, being from 90 to 150 inches per annum. The supply by this means would be 120,000,000 gallons daily, 12,000,000 gallons in excess of the present supply, and the supply would be constant; the length of the aqueduct would be 182 miles, and the cost would be 8,600,000*l*. This might easily be paid by a rate of 10d. in the pound on the metropolis. The lecturer found that at present he paid at the rate of 1s. 5d. in the pound for his water supply, so there would be no grievance on the score of cost. The water of Bala Lake was a specimen of this supply, and it would be superior to any in England as regards purity, and not inferior even to that of Glasgow at the present time.

The Westmoreland district would be the source of Messrs. Hemans and Hassard's supply. The lecturer found by reference that here a dry day was the exception. Of the 365 days of the year, it rained on 229 and 243 days respectively at two of the localities in the district, while at Borrowdale the number of rainy days was no less than 332. This water was received and stored in natural lakes. Three of these would be used—viz., Ulleswater, Thirlmere, and Haweswater.

The lecturer did not think that the beautiful scenery of the district would be interfered with by the necessary works. In favour of the scheme it might be stated that no large reservoirs would be required, but this saving was more than counterbalanced by the large amount of tunnelling that would be necessary. He did not think himself justified in giving opinions on the engineering points of the scheme, but he must mention that one such tunnel would be eight miles in length; the distance from the metropolis would be 240 miles. It would not be necessary to alter the beds of the lakes, but embankments would be required to adapt them for reservoirs. 200,000,000 gallons would be daily supplied to the metropolis, and 50,000,000 would be allowed for the large towns along the course of the aqueduct. The cost was greater than that of the other plan, being 12,200,000*l*., and the rate required would be equivalent to 1s. 1d. in the pound; this also is less than the present cost.

The quality of water from both sources of supply was excellent, and the preference could be given to neither. Specimens of both were exhibited on the table, taken during times of flood.

In reference to the chemical quality of the present supply, the lecturer said that the impurities are of two kinds—1st, those mechanically suspended only, and capable of removal by filtration; 2nd, those that are dissolved in the water. The quality of all the metropolitan waters varied in this respect from slight differences of filtration and storage by the various companies. The New River water was very similar to that of the Thames in February last as regards impurity, but the Kent water on evaporation gave a greater residue in each case. Large diagrams with comparative curves illustrated the matter that was expelled from water by temperature. The water of 1866 was much purer than that of 1865. Of the matters expelled by heat there were—1st, organic matter; 2nd, products of decomposition of certain salts, chiefly nitrates and nitrites; 3rd, ammonia and other volatile bodies. The process of ignition to drive off the organic matter and ammonia was shown by the lecturer, but there might be more organic matter in water than was shown by ignition. This manner of determination had long been thought unsatisfactory by chemists, and a more definite test was sought by the use of permanganate of potash, which was decolorised by organic matter. It was generally supposed that it would oxidise all organic matter in water. Some chemists even have used it as an absolute test. But, by definite experiments made by the lecturer, this method of estimation

is shown to be worthless. 3 grains of each of the following organic substances were introduced into some distilled water, and the permanganate test only estimated the following amounts :—

	Amount contained.	Amount estimated by permanganate.
Gum arabic.	3 grains	·082 grains
Cane sugar.	3 ,,	·051 ,,
Starch	3 ,,	·114 ,,
Gelatine	3 ,,	·634 ,,
Creatine	3 ,,	·064 ,,
Alcohol	3 ,,	·074 ,,
Urea	3 ,,	·074 ,,
Oxalic acid.	3 ,,	2·998 ,,

The only correct result being given by oxalic acid, the standard deoxidiser used. The same fact was illustrated to the audience by several large vessels containing water with various kinds of organic matter, and a definite measure of the permanganate was added to each until there was discoloration, when another measure was added, &c. The vessel that required most measures was a sample of water without any organic impurity whatever. These grave defects attending the above system induced him, with the valuable assistance of Mr. Armstrong, to replace it by a more precise and definite method. By these determinations they estimated the amount of organic matter, and also the hardness. They first determined the carbon and hydrogen by the ordinary methods; then the total nitrogen in the substance; then the nitrogen of the nitrates and nitrites separately; finally the nitrogen of the ammonia; and then deduced from these determinations the nitrogen of the organic matter. This nitrogen has long been insisted upon as of grave importance, but the suggestion before the present time had never been acted upon.

By tabulated results obtained by the above methods we could trace the history of the sewage contained in the water, past or present. As it travels along the stream, the carbon and hydrogen of the original impurity disappear by oxidation, forming water and carbonic acid, but the nitrogen is left like a skeleton, and from it we can trace its history. That which has been oxidised by the stream appears as nitrates and nitrites, and the amount still existing as organic nitrogen is found by deducting this from the sum total. An allowance has to be made for the nitrates and nitrites contained in ordinary rain-water; and when this correction was made, and the test applied to the metropolitan waters, not a trace of organic nitrogen was to be found. These results must be considered as very satisfactory.* A history of the water is thus obtained by its nitrogen. The hardness was determined by the usual soap test. Hardness is caused by the salts of magnesia and lime, but chiefly in London water by the lime dissolved by the carbonic acid in the water. This was illustrated by passing a current of carbonic acid through a vessel of lime-water. From this hardness a difficulty in washing the body is found, from the deposition in the pores of the skin of the insoluble stearate of lime. On entering a new district we can thus at once tell whether the water is hard or soft, by noticing the manner in which the people wash their hands. If the water be hard, they take their hands out of it to cleanse them from the curdling of the soap, but if it be soft the hands are kept and washed in the water. In conclusion, the lecturer said that, as it would be some time before any scheme could be available, it was most desirable, in the meantime, both to reduce still further the organic matter in water, and to obtain a constant supply. In fulfilling both of these requirements he could see no difficulty.

* Sewage contamination of water in 100,000 parts as estimated in 1866 :—

ACADEMY OF SCIENCES.

(FROM OUR OWN CORRESPONDENT.)

March 25, 1867.

M. EMILE DUCHEMIN communicated at the last meeting some very important observations on a thunder-stroke at Fecamp. The electric fluid did not spare the lighthouse, furnished with a lightning conductor, more than the houses in the town which were not thus provided. The gigantic electric spark passed through the tower, breaking everything in its course, even as far as the marble pavement, which it smashed before entering the earth. The evident cause of the inefficiency of the lightning-conductor was that its extremity was plunged into a cistern of waterlined by a thick coating of Portland cement.

M. Pouillet warmly thanked M. Duchemin, and declared that the chain was never put with his consent into a spot simply humid.

M. Guerin Menneville read a note on the eggs of silk-worms laid in South America, in Chili or Peru, and which possess the singular character of not being hatched for two years after being laid. On this occasion he ascertained that certain silkworms infected by the corpuscles discovered by M. Pasteur had given good results, whereas the eggs without corpuscles have failed; so that the only way of being sure of the good quality of the eggs is to obtain them from a country in which the epidemic has not broken out in the silkworms.

M. Darreste concluded, from the observations of monstrosities, that certain individual deformities can become the starting-point of an animal race; or, at any rate, that animals can be produced in the domestic line, presenting certain anomalies which reproduce very correctly the anatomic characters of another race. M. André Sanson protests against these combinations, and considers each species as absolutely fixed—that its characteristic is the reproduction of a determined type, as that of the species is of indefinite reproduction.

M. Dumas read a note upon the two masses of meteoric iron sent to the Museum of Natural History from North America; one is that sent from Mexico by Marshal Bazaine. These specimens of meteorological iron are remarkable by their white hue, softness, and the brilliant polish it takes.

M. Regnault presented, in the name of M. Deleuil, an excellent air-pump, of double action, exhausting and condensing, capable of creating a vacuum of one millimetre, also compressing to the pressure of five atmospheres. This unexpected success has been obtained by the application, under very improved conditions, of the system in which the piston is free and without any packing except a layer of air which separates it from the barrel of the pump. This layer of air is now only the $\frac{5}{10000}$th part of an inch; but M. Deleuil makes it very long by giving to the piston a length equal to three of its diameters. Its efficiency as an exhauster is thus greatly increased; the machine makes almost a complete vacuum, and preserves it indefinitely without the necessity of taking any of the parts asunder. The heat disengaged is not appreciable, or is reduced to that of the compression of the air. By making use of a thick pump barrel, M. Deleuil can obtain a pressure of eight to ten atmospheres. M. Regnault explained, and commented upon, the great progress realised by this experienced French instrument-maker—the more important as the use of the vacuum and of compressed air is every day becoming more general in the industrial arts.

M. Le Verrier announced that M. Gallos, director of the Observatory at Breslau, had determined the identity of the orbit of one of the swarms of shooting stars of April, of which the radiant point is well defined, with the comet of 1861.

Owing to the opening of the Paris Exhibition, the weekly meeting of the Academy was postponed from Monday to Tuesday last. Our report of the meeting arrived too late for insertion in this number.

NOTICES OF BOOKS.

Chemistry, Inorganic and Organic. With Experiments and a Comparison of Equivalent and Molecular Formulæ. By C. L. Bloxam, Professor of Practical Chemistry in King's College, London, &c., &c. 8vo. 1867. Churchill and Sons.

Two courses are open to the writer of the present day in the construction of an elementary treatise on chemistry. He may choose as his first object the presentation of a clear and comprehensive account of the modern theories by which the facts of the science are classified; or, regarding facts as of more importance than theories, he may assign to the latter a subordinate importance in his book, and strive mainly to incorporate the greatest possible number of those facts which he deems most important to his readers. Both classes of books are in the highest degree useful; but the method proper to each of them is essentially distinct. Few will venture to deny in the abstract that a systematic and scientific arrangement is best; but such an arrangement involves the devotion of so much space to theory and the description of so many compounds which are unimportant in themselves, and are simply interesting from their structural relations, that, unless the book is to be a very large one, practical details are sure to suffer.

Professor Bloxam has given us a most excellent and useful practical treatise. His 676 pages are crowded with facts and experiments, nearly all well chosen, and many quite new even to scientific men. He has the happy art of selecting the precise points which are likely to be useful to his readers, and describes them clearly in few words, without the omission of anything important. No faculty could be more important in a writer. How often do we meet with pretentious works published at four times the price of this one, in which a woful experience has taught us that we can always find everything except just the thing we want to know! Every one has in his library a dozen such books, and he soon learns to look upon them with scorn and aversion. On the other hand, we all know comparatively small works, which are kept always at hand, and to which we turn hopefully, even after failure in the pages of a bulky rival. It is high praise to say that Professor Bloxam's book will rank with such favoured friends, but we believe ourselves perfectly safe in asserting it. It is astonishing how much important information he often conveys in a few paragraphs. We might quote fifty instances of this, but will content ourselves with one or two as samples. Here is a portion of the author's account of the sulphuric acid manufacture:—

"The sulphuric acid is allowed to collect on the floor of the leaden chamber until it has a sp. gr. of 1·6, and contains 70 per cent. of oil of vitriol, HO,SO_3. If it were allowed to become more concentrated than this, it would absorb some of the nitric oxide in the chamber, so that it is now drawn off.

"This acid is quite strong enough for some of the applications of sulphuric acid, particularly for that which consumes the largest quantity in this country—namely, the conversion of common salt into sulphate of soda, as a preliminary step in the manufacture of carbonate of soda. To save the expense of transporting the acid for this purpose, the 'vitriol chambers' form part of the plant of the alkali works.

"To convert this weak acid into the ordinary oil of vitriol of commerce, it is run off into shallow leaden pans set in brickwork, and supported on iron bars over the flue of a furnace, where it is heated until so much water has evaporated that the sp. gr. of the acid has increased to 1·72. The concentration cannot be carried further in leaden pans, because the strong acid acts on the lead and converts it into sulphate—

$$2HO,SO_3 + Pb = PbO,SO_3 + 2HO + SO_2.$$

"The acid of 1·72 sp. gr. contains about 80 per cent. of true oil of vitriol HO,SO_3, and is largely employed for making superphosphate of lime, and in other rough chemical manufactures. It is technically called 'brown acid,' having acquired a brown colour from organic matter accidentally present in it.

"To convert this brown acid into commercial oil of vitriol, it is boiled down, either in glass retorts or platinum stills, when water distils over, accompanied by a little sulphuric acid, and the acid in the retort becomes colourless, the brown carbonaceous matter being oxidised by the strong sulphuric acid, with formation of carbonic and sulphurous acids. When dense white fumes of oil of vitriol begin to pass over, showing that all the superfluous water has been expelled, the acid is drawn off by a siphon.

"The very diluted acid which distils off is employed instead of water on the floor of the leaden chamber."—P. 205.

Details like these, abundant in all parts of the book, are particularly numerous in the descriptions of "the various substances employed in warlike stores;" and the accounts of gunpowder, guncotton, the metallurgy of iron and copper, the manufacture and properties of chlorate of potash, &c., leave nothing to desire. The section on gunpowder, which occupies fourteen pages, is particularly clear and complete.

But there is probably nothing in the book which will interest the practical chemist so much as the descriptions of lecture experiments which occur in almost every page. Every lecturer knows how constantly and eagerly he is compelled to look out for new experiments. The old ones become so hackneyed—we become so tired of the time-honoured charcoal in oxygen, and sugar turned into charcoal—that, were it only for our own sakes, we should hail any modification with delight. As a first-rate lecturer, Professor Bloxam has improved and altered the stock experiments until in some cases we hardly know them again. He is fertile in "dodges," and often illustrates a familiar fact by an experiment so simple and yet so pretty that we wonder we had not thought of it before. We will venture to quote a few which strike us, though it is very possible that some of them may have been borrowed by our author. It will be seen that some are but slight modifications of very familiar experiments.

Here is one which was first employed, we believe, by Professor Bloxam in a lecture at the Royal Institution some time ago:—

"By exposing a fragment of recently calcined wood charcoal under a jar filled with hydrosulphuric acid gas for a few minutes, so that it may become saturated with the gas, and then covering it with a jar of oxygen, the latter gas will act on the former with such energy that the latter will burst into vivid combustion. The jar must not be closed air-tight at the bottom, or the sudden expansion may burst it."—P. 58.

Many pretty illustrations of the nature of flame are given. We select three very simple ones:—

"Over an ordinary candle flame (Fig. 1) a tube may be adjusted so as to convey the finely divided carbon from the luminous portion of the flame into the flame of hydrogen, which will thus be rendered as luminous as the candle flame, the dark colour of the carbon being apparent in its passage through the tube."

Fig. 1.

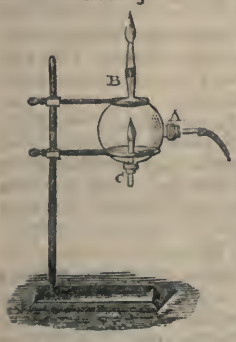
"A bottle furnished with two straight tubes (Fig. 2) is connected with a reservoir of hydrogen. One of the tubes is pro-

Fig. 2.

vided with a small piece of wider tube containing a tuft of cotton wool. On kindling the gas at the orifice of each tube, no difference will be seen in the flames until a drop of benzol ($C_{12}H_6$) is placed upon the cotton, when its vapour, mingling with the hydrogen, will furnish enough carbon to render the flame brilliantly luminous."

"A quart glass globe with three necks is connected at A (Fig. 3) with the gas pipe [coal-gas] by a vulcanised tube. The second neck (B) at the upper part of the globe is connected by a short piece of vulcanised tube with a piece of glass tube about ½ inch wide, from which the gas may be burnt. Into the third and lowermost neck is inserted, by means of a cork, a thin brass tube C (an old cork-borer) about ⅓ inch in diameter. When the gas is turned on, it may be lighted at the upper neck, and if a lighted match be then quickly thrust up the tube C the air which enters it will take fire and burn inside the globe."—Pp. 94-95.

Fig. 3.



The next experiment we will quote is analogous to the last, and might well accompany it in a lecture:—

"If a little chlorate of potash be melted in a deflagrating spoon, and plunged into a bottle or flask containing coal-gas, the salt burns with great brilliancy, its oxygen combining with the carbon and hydrogen in the gas, which becomes in this case the *supporter of combustion*."—P. 158.

Our readers will not have failed to notice in these short extracts the extreme conciseness and clearness of Professor Bloxam's style. He writes very much as he lectures, and we can hardly give higher praise.

The old equivalents are adopted throughout the book, though the new system is described and used here and there for special purposes. The author tells us in his preface that he adopted this course from the difficulty of deciding which of the more advanced systems now employed by chemists was entitled to a preference. With regard to formulæ, this difficulty is no doubt most formidable, and every teacher who cares for his pupils' interest must, unless he be a very firm adherent of some one system, look upon it with anxiety and doubt. But this does not extend to the use of atomic weights, and when we consider the great advantages of a general agreement upon this latter point, we cannot but regret that Professor Bloxam has thought it right to retain the old numbers. The adoption of 16 as the atomic weight of oxygen does not necessitate the use of any particular set of formulæ.

As to arrangement, we have already expressed our opinion that the convenient and practical, though somewhat unscientific, method adopted by our author, is, on the whole, well suited to the book. The advantages and disadvantages of the method are seen very strikingly in the section on organic chemistry, which occupies 200 pages of the book. It is very convenient to be able to turn to a chapter on the products of the distillation of coal, and there to find all the mediate and immediate derivatives of tar, from benzol, phenic acid, and naphthaline to the aniline colours and picric acid; and then, turning over a few pages, to be able to compare them with the compounds similarly obtained from wood. But, to balance this advantage, we often find it next to impossible to discover a compound without the use of the index, as, for instance, in the case of methyl, ethyl, and allyl alcohols, which are described in quite different sections of the book. And we must admit some disadvantages in a system which compels us to study the benzoyl and salicyl series, aniline, the nitro-prussides, phenyl-alcohol, and the glucosides, before we are introduced to common alcohol. We do not say that Professor Bloxam is to blame for these defects. They are to a great extent inseparable from the system he has adopted, and they are, in a great part, atoned for by one of the fullest and best indexes we have ever seen—an index which not only gives the common as well as the scientific name of a substance, sometimes in several places, but also includes symbols and many of the most important formulæ, so that the student who looks for $C_{12}H_7N$, will not only be directed to page 455, but will also be informed that it is called aniline.

We close our notice with regret, for Professor Bloxam's book is one which makes criticism a pleasant task.

CONTEMPORARY SCIENTIFIC PRESS.

Under this heading it is intended to give the titles of all the chemical papers which are published in the principal scientific periodicals of the Continent. Articles which are merely reprints or abstracts of papers already noticed will be omitted. Abstracts of the more important papers here announced will appear in future numbers of the Chemical News.]

CORRESPONDENCE.

Estimation of Nitric Acid in Well-water and Manures.

To the Editor of the Chemical News.

Sir,—In last week's number of the Chemical News I notice a method of Mr. Horsley's for the estimation of nitric acid in well-water, which appears to me to be a needlessly long and tedious one. I have found the following method to give good results:—Evaporate a quarter or half a gallon of the water under examination to the bulk of about 6 ounces; filter and wash. To the filtrate add pure Na_2CO_3 in sufficient quantity to precipitate all the lime and most of the magnesia, &c., taking care not to add a great excess; otherwise the effervescence produced by the addition of HCl in the next stage of the

process is apt to project some of the residue from the basin. When too much Na_2CO_3 has been added, it is better to add HCl to the filtrate till nearly neutral, stopping short when the solution is still alkaline. The alkaline solution is now evaporated to dryness, 50 grs. of As_2O_3 added, and the whole dissolved in concentrated HCl and evaporated to dryness. The remainder of the process is conducted according to the arsenious acid method for the determination of N_2O_5, given in Fresenius, using ammoniacal chloride instead of ammoniacal sulphate of magnesium. As the As_2O_3 may contain a little As_2O_5, 50 grs. are treated as above, and the amount of arseniate of magnesium and ammonium deducted from that previously found. The As_2O_3 I have just now gives ·50 per cent. $2MgO,(NH_4)_2O,H_2O,As_2O_5$.

Nitric acid in manures may also be estimated by this method, with a slight modification. Thus, if the manure is in a fine state of division, 20 grs. are heated to boiling with 5 or 6 ounces of H_2O, filtered, and washed. The filtrate is then treated with a solution of $CaCl_2$ (a quantity equal to 5 or 6 grs. of $CaCO_3$ is usually sufficient to give lime to all the P_2O_5 present), carbonate of sodium added in slight excess, and the process otherwise conducted as given above. Should the sample, however, be so damp that it cannot be brought into a state of fine division—as is usually the case—100 grs. are used, and the solution filtered and washed into a 5000-grain flask, and filled up to the mark with H_2O. 1000 grs. of this solution, corresponding to 20 grs. of the original sample, are now, after having been well shaken, treated with $CaCl_2$ and Na_2CO_3, as above described.

I am, &c. T. L. PATTERSON.

Greenock, March 27.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Synthesis of Organic Acids (C=12, O=16).—L. Carius. To a mixture of benzol and dilute sulphuric acid at 18°, potassic chlorate is added in very small quantities, the liquid is shaken with ether, the ether gives up on evaporation an acid of the formula $C_6H_7Cl_3O_5$, trichlorphenomalic acid, a trichloro-substituted homologue of malic acid, soluble in water and alcohol, crystallisable, melting at 131—132°. At a few degrees above its fusing point it decomposes, giving rise to another acid now under examination. If shaken with water and zinc powder, it parts with its chlorine, and passes into an amorphous easily soluble tribasic acid, much resembling some of the bodies connected with the sugars, and which may be called phenomalic acid $C_6H_{10}O_5$.

By vigorous action of nascent hydrogen on trichlorphenomalic acid, adipic acid should be produced, but in its stead appears succinic acid identical with that from acknowledged sources.

Trichlorphenomalic acid parts with its chlorine on the slightest provocation; simple ebullition in water is sufficient to decompose it, at least in part. If to its aqueous solution baryta water be added in excess, and the liquid be heated for some time, phenaconic acid, $C_6H_6O_6$, is formed, metameric with aconitic acid and polymeric with fumaric acid. Phenaconic acid is crystallisable, does not decompose below 170°, may be sublimed at a slightly higher temperature, but decomposes if suddenly heated; if boiled with nitric acid it yields oxalic acid, but no nitrocompound; its molecule contains H_3 basylous; all its salts are crystallisable, and most of them are soluble in water.

In the preparation of trichlorphenomalic acid there are also obtained oxalic acid, an uncrystallisable chlorinetted acid, apparently of similar constitution to trichlorphenomalic acid, possibly monochlorbenzol, and some tar-like bodies.—(*Sitzungsber. d. Gesellschaft. d. g. Naturwissensch.*, 1867, 21.)

Hydrocarbon, a New (C=12).—C. Friedel and A. Ladenburg. The existence of silicium ethyl, containing one atom of silicium and four molecules of ethyl, and having the functions of a saturated hydrocarbon, pointed to an analogous compound in which silicium should be replaced by carbon, which carbon would therefore be saturated by carbon alone. In the same manner as primary, secondary, and tertiary alcohols contain each of them one carbon atom, the four bonds of which are partly saturated respectively by one, two, and three bonds of other carbon atoms, and as these different alcohols may be referred to hydrocarbons of analogous constitution, so it may be presumed that a quaternary hydrocarbon may exist, in which one carbon atom will be saturated exclusively by other four carbon atoms.

In methylchloracetol, resulting from the action of phosphoric pentachloride on acetone, it is most probable that one carbon atom is united with two carbon atoms and two chlorine atoms; if, therefore, the two chlorine atoms be replaced by two hydrocarbon radicles, the quaternary hydrocarbon sought for will be obtained.

Zinc-ethyl, heated with methylchloracetol, gives rise to enormous quantities of gas — probably propylen and ethylen. The greater part of the residue, when freed from excess of zinc-ethyl and further purified, boils between 86° and 90°, and is hydride of heptyl C_7H_{16}, or, as it may be called from the mode of its formation, carbodimethyldiethyl.—(*Bull. Soc. Chim. Paris*, 1867, 65.)

Hydrocarbons, their Compounds with Picric Acid.—M. Berthelot. These compounds are produced with much difficulty, being decomposed by excess of the solvent used. It is indispensable to success that they separate from a liquid previously saturated by the parent substances; but each hydrocarbon requires the adoption of special artifices. In general, the most fit solution of picric acid is an alcoholic one, saturated at 20°—30°. The most easily obtained is the naphthalen compound. The naphthalen, reten, anthracen, chrysen, and benzerythren compounds are described. An article on the qualitative separation of hydrocarbons by means of picric acid concludes a paper replete with details of operating.—(*Bull. Soc. Chim. Paris*, 1867, 30.)

Camphor, Action of Sodium on.—H. Baubigny. Camphor dissolved in toluol is violently attacked by sodium at 90°; but the reaction can only be explained by the supposition that hydrogen is replaced by sodium in one portion of camphor, and in the nascent state combines with another portion of camphor, converting it into borneol, the result of the reaction. A full account is promised of two homologues of ethylcamphor — namely, methyl- and amyl-camphor, the properties of which resemble those of ethylcamphor. Methylcamphor boils at about 194° (corr. at 733 millim.). Amylcamphor boils at about 277° (corr. at 736 millim.).—(*Zeitschr. Chem.*, N. F., iii. 71.)

Glycerin, Crystallisation of.—To an account of the observation by Crookes (CHEM. NEWS, xv. 26) of the crystallisation of glycerin under peculiar circumstances, Fittig appends a note stating that a manufacturer at Vienna has also observed the same phenomenon, occurring, however, under different conditions; and as in this case the glycerin had been in an iron tank for more than a year, and was impure at the outset, it has been suggested that the solidification might be connected with the presence of iron in solution.—(*Zeitschr. Chem.*, N. F., iii. 70.)

Potassium, Separation from Sodium, &c.—R. Finkener. To separate potassium from sodium when in presence of sulphuric acid, Finkener proposes the following:—Add chlorhydric acid to the aqueous solution to be analysed; then solution of platinic chloride until the liquid is deep yellow. Add water sufficient, when

boiling, to dissolve the double salt precipitated; evaporate to syrupy consistence, but not dry; extract, and wash on a filter with a mixture of alcohol (specific gravity ·8) 2 volumes, ether 1 volume; decompose, and wash out all the sodic sulphate on the filter with a solution of ammonic chloride. The filtrate, alcoholic extract, and washings contain the sodium. Heat the filter and its contents in a stream of hydrogen—a temperature of 240° suffices; extract the potassic chloride with water, and weigh or titrate with silver solution.

A great excess of sulphuric acid is to be avoided. The ammonic chloride solution dissolves about ·13 to ·26 per cent. of the platino-potassic chloride, but the quantity so lost varies with the strength of the solution, its temperature, and the quantity of free chlorhydric acid in it. On the other hand, the double salt carries down with it about ·16—·35 per cent. sodic salt. Potassium may in like manner be separated from lithium. If potassium, sodium, and lithium are present in the same solution, first separate lithium as lithic phosphate, and then proceed as above, or convert the three into platino-chlorides, extract the sodic and lithic salts with a mixture of alcohol and ether containing a little chlorhydric acid, and wash with a mixture of absolute alcohol 6 volumes, ether 1 volume; the residue is pure platino-potassic chloride. Direct experiments showed that the above method is not vitiated in any degree by the presence of chlorhydric, nitric, phosphoric, arsenic, or boric acids, or salts of magnesium, zinc, manganese, iron, aluminium, nickel, copper.—(*Pogg. Ann.* cxxix. 637.)

Chrysen and Anthracen (C=6).—M. Berthelot. Laurent's pyren is probably identical with Fritsche and Anderson's anthracen, and if Dumas' paranaphthalen is not the same body, it is homologous with it. It is proposed to confine the name chrysen to the hydrocarbon $C_{36}H_{12}$, derived from benzol, described (*Ann. Chim. Phys.*, S. 4, ix. 457). Anthracen is obtained from crude anthracen by distillation, and crystallisation from alcohol; it boils at about 320—330°, and melts somewhere about 213°. A thermometer plunged in melted anthracen does not always indicate the same temperature on the solidification of this body; the melting point varies with the treatment to which the body has been subjected. In passing from the solid to the liquid state, anthracen appears to be capable of taking up an unlimited number of transitory states of equilibrium. It acquires a condition of stable equilibrium only when it is raised to a temperature much above that of fusion. Anthracen has a disagreeable and irritating odour, and, in spite of its high boiling point, evaporates so readily that it is difficult to melt a few grammes of it in a capsule. Its formula is $C_{28}H_{10}$.

The fractions of crude anthracen distilling above 350°, consist probably of homologues of anthracen, among others methylanthracen, which is most likely identical with Dumas' paranaphthalen, tetramethylanthracen, or reten, chrysen, and benzerythren. Methylanthracen and reten, although boiling at a far higher temperature than anthracen, fuse at a lower temperature than that body: thus reten, $C_{36}H_{18}$, differing from anthracen by $4C_2H_2$, melts at 95°; anthracen, $C_{28}H_{10}$, melts at 213°; methylanthracen, $C_{30}H_{12}$ (paranaphthalen), melts at about 180°. Reten and its picrate are more soluble in alcohol than anthracen or its picrate. The anomalous behaviour of these homologues of anthracen is perhaps due to the rapid increase in their percentage of hydrogen—reten containing H 7·7 per cent.; methylanthracen H 6·3 per cent., anthracen H 5·6 per cent. They may, particularly reten, be regarded as formed by the association of two hydrocarbons—anthracen, and a hydrocarbon of the $C_{2n}H_{2n}$ series. The physical properties of reten are about the mean of those of these proximate constituents.

Six fractionations of crude anthracen separate a hydrocarbon boiling at about 260°. More soluble in alcohol, and crystallising itself and its picrate more easily, than anthracen, it cannot be mistaken for that body; nor is it naphthalen, which is more volatile and together with its picrate more crystalline; nor is it phenyl, which does not combine with picric acid. It resembles a body obtained in small quantity by the reaction of ethylen on benzol.—(*Bull. Soc. Chim. Paris*, 1867, 43.)

MISCELLANEOUS.

The Annual Dinner of the Chemical Society.—In accordance with a happy suggestion made at one of the recent meetings of the Society that a public dinner should take place some time before the anniversary meeting, nearly 100 of the Fellows assembled on Wednesday, the 27th ult., at the Albion Tavern, Aldersgate-street, for the purpose of thus instituting some researches on the chemistry of digestion. Dr. Miller, President of the Society, occupied the chair. Amongst the visitors we noticed Brigadier-General J. H. Lefroy, R.A., F.R.S., Lieutenant-Colonel W. F. De la Rue, Professor Stokes, Sec. R.S., Professor Tyndall, F.R.S., Professor Morris, F.R.S., and some others; whilst to enumerate the Fellows of the Society would be to copy from the list nearly all the leading members with but few exceptions. After the usual loyal toasts, the President proposed the "Army, Navy, and Volunteers," associating with it the name of General Lefroy. General Lefroy, who was received with cheers, expressed himself much flattered by the cordial reception he had met with from the many eminent scientific men he saw around him. The profession to which he belonged owed much to the sciences, but particularly to chemical science, from the first application of "villanous saltpetre." He felt convinced, although much had been done in the application of chemical science to the arts of warfare, that still greater applications remained to be discovered, and he considered that a knowledge of chemistry was now indispensable to all those who meant to take up the profession of arms. The chairman then proposed "The Royal and other learned Societies," which was responded to by the Secretary of the Royal Society. Professor Stokes returned thanks on behalf of the Royal Society, and reminded the meeting that it was the oldest of the learned bodies, and embraced all the leading sciences. The progress since made in the various departments of science had compelled philosophers to found special societies, but they might be regarded as offshoots from one parent stem, and he congratulated the members generally upon the great cordiality which existed among the learned bodies. In reply to the toast, "The Chemical Society," Professor Williamson, after speaking of the important position which this Society had attained, which had caused it repeatedly to outgrow the accommodation allotted to it, congratulated the Fellows on the very excellent accommodation which had been allotted to them by Messrs. Banks and Barry in the plans lately submitted to Government for the accommodation of the learned societies on the space situated between Burlington House and Piccadilly. One detail, he was sure, would give satisfaction to every one—the library was to be on a different floor from the meeting rooms. Now he considered that one very important object supplied by these evening meetings of the learned societies was the opportunities which they allowed of investigators who wished for special information on any subject to go to the meeting and "turn up" any particular friend who might be strong on that point, and extract all the information he could out of him. This practice of appealing to living, instead of dead, volumes had gradually given rise to a small supplementary meeting of chemists outside the regular meeting-room, and it frequently happened that an animated discussion in the one slightly interfered with the appreciation of a learned paper in the other. It would therefore be a great satisfaction to many present to know that, the two rooms being on different floors, the more animated meeting

could assemble without having their consciences disturbed by entreating messages from the Secretary to make a little less noise. The next toast was "The President elect," in reply to which Dr. Warren de la Rue, who was received with great applause, reminded the meeting that he was not yet the President elect, but rather the President *select*, or *possible* President. He regretted that he had not done more for science, but he possessed an ardent love for it in all its branches, and every moment he could spare from business he devoted to its service. Should he be honoured by being elected President, he would endeavour to promote the interests of the Chemical Society in every possible way. The next toast was the "Visitors," which was briefly responded to by Professor Tyndall; he felt with shame that he was there as a visitor instead of a Fellow, but he assured the meeting that this was from no want of love for chemical science or of appreciation of the advantages to be derived from attending its meetings, but it was entirely due to the fact that, amidst the engrossing investigations which occupied his time, the duty which he owed of applying for admission to the Fellowship had not presented itself to him with sufficient prominence. He spoke in warm terms of commendation of the treat which he had experienced that evening in the practical illustration he had had of "sonorous vibrations," a subject which, however deeply he might experiment upon it, he could never of himself illustrate in so pleasing a manner. The other toasts were the "Officers," which were replied to by Drs. Odling, Redwood, and A. V. Harcourt, Esq. The sonorous vibrations referred to by Professor Tyndall were the very excellent musical interludes with which the toasts were alternated. These consisted of the National Anthem, sung by Mr. Spiller, accompanied by Professor Abel on the pianoforte; comic song, by Colonel De la Rue; four-part songs "Oh! who will o'er the downs," and "O hills, O vales of pleasure," by Messrs. Brown, Williams, Spiller, and Bassett; a pianoforte solo *potpourri*, by Professor Abel; and a German chorus, "Das Morgenroth," sung by Drs. Hugo Müller, Sprengel, Francis, Russell, Roscoe, and Tyndall. The song of the evening, however, was Mr. Field's "The Chemists' Dinner." The happy manner in which the author, by a few appropriate allusions, referred to one chemical celebrity after another, presenting each in his own characteristic peculiarity, without saying a word which could give offence to any one, shows that the author's tact and geniality are of as sterling a character as his poetical and chemical attainments.

Paris Exhibition.—The following is a list of jurors and associates appointed for the various Classes in which our readers are likely to take most interest. Class 7. Paper stationery, binding, painting and drawing materials; juror, Mr. Warren De la Rue, F.R.S.; associate juror, Mr. F. Hankey. Class 9. Photographic proofs and apparatus; juror, Dr. Hugh W. Diamond; associate juror, Lieutenant-Colonel Gordon, C.B., R.E. Class 11. Medical and surgical instruments and apparatus; juror, Sir J. F. Olliffe, M.D. Class 12. Mathematical instruments and apparatus for teaching science; juror, Mr. C. Brooke, M.A., F.R.S.; associate juror, Lieutenant-Colonel Strange, F.R.S., F.R.A.S. Class 24. Apparatus and processes for heating and lighting; juror, Professor J. Tyndall, LL.D., F.R.S.; associate juror, Rear-Admiral Ryder, C.B., R.N. Class 25. Perfumery; juror, Dr. W. Odling. Class 36. Jewelry and precious stones; juror, Earl Dudley; associate juror, Mr. N. H. M. S. Maskelyne. Class 40. Mining and metallurgy; juror, Mr. S. H. Blackwell; associate juror, Captain W. S. Roden. Class 41. Products of the cultivation of forests, and of the trades appertaining thereto; juror, Hon. F. D. M'Gee; associate juror, Mr. P. L. Simmonds. Class 43. Agricultural products (not used as food) easily preserved; juror, Mr. D. Hanbury; associate juror, Dr. T. Thomson, F.R.S. Class 44. Chemical and pharmaceutical products; juror, Dr. Frankland, F.R.S.; associate juror, Dr. David Price. Class 45. Woolloton. Class 72. Condiments and stimulants; sugar and confectionary; juror, Mr. G. Moffatt, M.P. Class 73. Fermented drinks; juror, Hon. H. G. Howard; associate juror, Mr. E. L. Beckwith.

Meetings for the Week.

Monday, April 8.

Royal Medical and Chirurgical Society, 8½ p.m.

Tuesday, April 9.

Royal Institution, 3 p.m. Rev. G. Henslow "*On Botany.*"

Photographic Society, 8 p.m.

Thursday, April 11.

Royal Institution, 3 p.m. W. Pengelly, Esq., "*On the Antiquity of Man.*"

Royal Society, 8½ p.m.

Friday, April 12.

Royal Institution, 8 p.m. Mr. Balfour Stewart, F.R.S., "*The Sun as a Variable Star.*"

Saturday, April 13.

Royal Institution, 3 p.m. W. Pengelly, Esq., "*On the Antiquity of Man.*"

ANSWERS TO CORRESPONDENTS.

*** All *Editorial Communications* are to be addressed to the Editor and *Advertisements* and *Business Communications* to the Publisher, at the Office, 1, Wine Office Court, Fleet Street, London, E.C. *Private* letters for the Editor must be so marked.

J. H. Swindells.—Received with thanks.

An Old Subscriber.—We will forward the request to our Paris correspondent, who will doubtless attend to it.

R. C. C., &c.—We shall be glad to receive a condensed account of the more salient points of the results of your observations quarterly; but please make them short, and avoid tables if possible.

J. W. Y.—Your paper is received with thanks. It shall be inserted next week if possible.

A. B. wishes to know whether anywhere in this country illuminating gas is produced by conducting a current of air through volatile hydrocarbons; if so, with what practical success, and with what kind of hydrocarbons.

J. W. wishes to know what is the colouring matter in commercial acetate of alumina. He will find the prices of drugs and chemicals regularly quoted in the *Public Ledger*. Iron liquor is made by heating 20 gallons of acetate of lime liquor at 24° Twaddell in a copper to 140° F. Then add 65 lbs. of green copperas in coarse powder, and stir till dissolved. Finally add 2½ gallons of common pyroligneous acid. The product will be 16 gallons of iron liquor at 16° Twaddell.

A Constant Reader.—We feel obliged to decline the article in its present form. If you will rewrite it, very much condensed, we will try and find room for it, but the demands on our space are now so great that we are obliged to insist upon brevity in all such articles as this one.

Microscopist.—Santonine, salicine, and cinchonidine are very beautiful objects for the microscope, when viewed by polarised light. The best method of mounting each is not described in books. Probably allowing a strong alcoholic solution to dry, or fusing some on the slide, and subsequent mounting in Canada balsam, would give you good results. If any of our correspondents have had experience in these matters, we shall feel obliged if they will favour us with a few details.

Horsley's Powder.—This consists of three parts of chlorate of potassium and one of gall-nuts, ground, dried, and sifted together. We have had an account of some experiments forwarded to us, from which it appears that, volume for volume, the disruptive force of this powder is fifteen times greater than that of gunpowder. We fear, however, that the great danger of all explosive materials in which chlorate of potash is used will prevent a powder of this kind from coming into general use.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On the Application of the Blowpipe to the Quantitative Determination or Assay of certain Metals, by David Forbes, *F.R.S., &c.**

(*Continued from page* 166.)

Cupellation.—The bone ash required for this process should be of the best quality and in the most impalpable powder, prepared by elutriating finely-ground bone ash, and drying the product before use.

The cupel still hot from the last operation is placed upon the anvil, and the crust of litharge, with its enclosed metallic bead, gently removed, leaving the hot coarse bone ash beneath it in the mould; upon this a small quantity of the elutriated bone ash is placed, so as to fill up the cavity, and the whole whilst hot stamped down by the bolt, previously slightly warmed, with a few taps of the hammer. The cupel thus formed is heated strongly in the oxidating flame, which should leave the surface perfectly smooth, and free from any fissures or scales; if such appear, the bolt must again be used, and the cupel re-heated. In this process it is very important that the cupel should possess as smooth a surface as possible, whilst at the same time the substance of the cupel beneath should not be too compact, so as thereby to permit the litharge to filter through and be readily absorbed, leaving the silver bead upon the smooth upper surface.

The bead of silver-lead obtained from the last operation is taken out of the litharge in which it is embedded, and, after removing any trace of adherent bone ash or litharge, is slightly flattened to prevent its rolling about upon the surface of the cupel.

It is now put into the cupel prepared as before described, placing it on the side furthest from the lamp and a little above the centre of the cupel, which is now inclined slightly towards the lamp, and is heated by the oxidating flame directed downwards upon it, this causing the globule when fused and oxidating to move of itself into the centre of the cupel. The cupel is now brought into a horizontal position, and the flame, directed on to it at an angle of about forty-five degrees, is made to play upon the bone-ash surface immediately surrounding the globule, without, however, touching it, so as to keep this part of the cupel at a red heat sufficiently strong to insure the globule being in constant oxidising fusion, at the same time to cause the perfect absorption of the litharge, so as to prevent any scales of litharge forming upon the surface of the cupel under the globule, which would impede the oxidation, as well as prevent the silver bead being easily detached at the conclusion of the operation. Should the heat at any time be too low and the globule solidify, it must be touched for an instant with the point of the flame and proceeded with as before. Should (in consequence of the bone ash not having been sufficiently heated to absorb the litharge perfectly) a little litharge adhere pertinaciously to the globule, or a particle of the bone-ash cupel attach itself, the cupel should be slightly inclined, so as to allow the globule to move by its own weight on to another and clean part of the cupel, leaving the litharge or bone ash behind it; but, if not sufficiently heavy to do so, a small piece of pure lead may be fused to it in order to increase its weight, and so allow of the same proceeding being adopted.

By slightly inclining the cupel stand, and moving it so as to present in turn all parts of the surface surrounding the globule to the action of the flame, the cupellation proceeds rapidly. If, however, the assay contains very little silver, it will be found necessary to move the globule from one spot to another on the cupel, in order to present a fresh surface for absorbing the litharge formed; this is done by simply inclining the cupel stand, remembering that the bone ash surrounding the globule must always be kept at a red heat, without ever touching the globule itself by the flame.

In assays rich in silver a play of iridescent colours appears some seconds before the "brightening," which disappears the moment the silver becomes pure; as soon as this is observed the cupel should be moved in a circular manner, so that the globule is nearly touched all round by the point of the blue flame, and this is continued until the surface of the melted silver is seen to be quite free from any litharge, upon which it is very gradually withdrawn from the flame so as to cool the assay by degrees very slowly, in order to prevent "spitting."

When the silver-lead is very poor, this play of colours is not apparent, and as soon as the rotatory movement of the globule ceases, the heat must be increased for an instant in order to remove the last thin but pertinacious film or scale of litharge, and subsequently the assay is cooled gradually; when cold it should, whilst still upon the cupel, be examined by a lens to see whether the bead possesses a pure silver colour, as if not it must be re-heated.

Frequently, when the "brightening" takes place, the silver globule is found to spread out, and, after cooling, although of a white colour, is found to appear somewhat less spherical or more flattened in shape than a corresponding globule of pure silver would be. This arises from the presence of copper still remaining in the silver, and in such cases a small piece of pure lead (about from one-half to one and a half grain in weight, according to size of assay) should be fused on the cupel along with the silver, and the cupellation of the whole conducted as before on another part of the cupel, when the silver globule will be obtained pure and nearly spherical in shape. Sometimes the silver globule in "brightening" may still remain covered with a thin film of litharge, although otherwise pure; this arises from too little heat having been employed in the last stage of the operation, and consequently the bead should be re-heated in a strong oxidating flame until this litharge is absorbed, and the globule, after slow cooling, appears pure.

If the instructions here given be strictly attended to, it will be found after some practice, that very accurate results may be obtained in the blowpipe assay for silver, and that no difficulty will be found in detecting the presence and determining the amount of silver present, even when in as small a quantity as half an ounce to the ton. When substances containing very little silver or less than that amount are examined, several assays should be made, and the silver-lead obtained concentrated separately, after which the various globules should be united and cupelled together in one operation.

It is hardly necessary to remark that the lead employed in assaying should be free from silver, or, if not, its actual contents in silver should be determined, and subtracted from the amount found in the assay.

Assay lead containing less than one quarter of an ounce to the ton of lead can readily be obtained, or can be made by precipitating a solution of acetate of lead by metallic zinc, rejecting the first portion of lead thrown down. In all cases the lead should be fused and granulated finely—the granulated lead for use in these assays being previously passed through a sieve containing forty

* Communicated by the author.

holes to the linear inch. It is also useful to have some lead in the form of wire, as being very convenient for adding in small portions to assays when on the cupel.

On the Separation of Lanthanum and Didymium, by M. Cl. Winckler.

The separation of cerium from lanthanum and didymium is easily effected, but this is not the case with regard to the mutual separation of the last two metals. The author has recently proposed to separate and estimate cerium by binoxide of mercury and permanganate of potash. He has since ascertained that cerium is not in this case merely precipitated in the state of a peroxide, but is accompanied by didymium, whilst the lanthanum remains in solution. The estimation of oxide of cerium is very little altered, for it gains by its oxidation 5·88 per cent. in weight, whilst didymium only gains 0·38 per cent. in changing from a protoxide to a peroxide ($D_{32}O_{33}$). This is an excellent method for separating didymium from lanthanum.

To find the didymium which accompanies the cerium in its precipitation by permanganate of potash, redissolve the precipitate in hydrochloric acid. After having well calcined it to free it from the oxide of mercury, evaporate the hydrochloric solution to dryness in the presence of sulphuric acid; dissolve the residue of sulphate in water, and add sulphate of potash to it. In twenty-four hours a double sulphate separates, insoluble in sulphate of potash.

$$KO,SO_3 + \left.\begin{matrix}Ce\\Di\end{matrix}\right\} O,SO_3.$$

The precipitate must then be dissolved in water, and the sulphates changed to oxalates, which must be calcined to obtain the oxides of cerium and didymium, which are then separated in the usual way.

The lanthanum in the filtered liquid may be obtained thus:—First treat the filtered liquid with sulphuretted hydrogen, to separate the oxide of mercury, then precipitate the lanthanum as an oxalate, and calcine it. The oxide of lanthanum then contains very little didymium.—*Journal für praktische Chemie*, xcv. 410.

On some Lecture Experiments, by Professor F. Wöhler.

Silicated Hydrogen Gas.—The following apparatus may be used to show that this gas inflames spontaneously and will furnish rings of silicic acid, when using only a small quantity of material.

A two-necked flask holding from 400 to 500 cubic centimetres is filled with water which has been boiled and allowed to cool. To the lateral neck is fixed a small tube, bent to a right angle, and terminated by a little bulb; a tap is fitted to this, to which may be joined by india-rubber a straight drawn-out tube for the escape of the gas. The little bulb must be filled with water. To the centre tubulure is fixed, by means of a cork, a vertical tube having several bulbs in it, and ending in a funnel; and its lower end is contracted and bent so as to prevent the passage of the gas. The pulverised mass is introduced by this tube, care being taken that no air enters at the same time. Pour the concentrated hydrochloric acid in by the large tube, always avoiding the entrance of the air, which causes dangerous explosions. By inclining the apparatus it is easy to make the water run out of the little ball near the tap, and to fill it with gas; the ball is merely to hold the scum formed during the reaction. The large tube should hold almost as much as the flask; were it not so, the excess of liquid might easily be taken away—by a small pipette, for instance.

To insure success in the preparation of the matter containing the silicide of magnesium, too much heat must not be applied after the action of the sodium has taken place; the heat used for the preparation of magnesium suits in this case—only the black pieces filled with little metallic particles should be used, coarsely pulverised. Too finely powdered, they give rise to a great deal of scum.

Liquid Sulphurous Acid.—In using the following apparatus the great cold produced by the evaporation of liquefied sulphurous acid may be rendered sensible without inhaling the gas. The apparatus is entirely of glass, and is composed of a tube with enlargements, terminated at its two extremities by two narrower vertical branches, each furnished with a tap, so that the communication between the interior and the atmosphere may be established or interrupted at will. To fill this recipient, after having plunged it into a mixture of snow and salt, introduce dry gas by one of the taps until the liquefied product fills it about two-thirds; by then shutting the taps the liquid may be preserved as long as is desired. To determine the evaporation of the liquid, adapt to the taps tubes bent to a right angle, and plunge them into cylinders filled with water; open the taps by degrees; the acid which volatilises is entirely absorbed by the water, whilst the liquid part is so cooled that the reservoir of the apparatus condenses the moisture of the air and covers it with a layer of ice. The evaporation, of course, takes place very slowly.

The experiment may be tried in a more simple way. Place a tube, about twelve inches long and half an inch in diameter, closed at one end and drawn out at the other, in a freezing mixture, and fill it three parts with liquid sulphurous acid. Keeping the tube in the freezing mixture, seal up the narrow end before the blowpipe. To determine the evaporation of the liquid acid, incline the tube; adapt to it, by means of caoutchoue, a tube bent at right angles, and plunged in water; then break the point of the tube with blunt pincers.

TECHNICAL CHEMISTRY.

Manufacture of Sulphate of Magnesia, by J. H. Swindells.*

I notice in a recent number of the Chemical News that M. Mirns prepares sulphate of magnesia from the residuals of the manufacture of carbonic acid from magnesite and sulphuric acid. This method is hardly new, and is, I think, scarcely worth the trouble expended upon it. It must be borne in mind that this salt is not now used exclusively as "a useful purgative," and "also for agricultural purposes," as we are informed even in recent works on manufacturing chemistry.

Few people are aware that Epsom salt is now made on a very large scale for the use of warp-sizers. Something like 150 tons per week are disposed of in Manchester for this purpose alone. Perhaps a short account of the manufacture of sulphate of magnesia as now carried on may be of interest to some of your readers, and they can then compare the present method of making it with the past. I will merely give the practical part, leaving the theoretical to your readers.

The plant required consists of—1. A digester, a square wooden box lined with thick sheet lead; on the bottom and about three feet up the sides flags are placed so as

* Communicated by the author.

to protect the lead from the effects of the magnesian limestone, which often shakes about very much. This digester is made of various sizes. 2. A settler, made either of lead or flags well cemented together. Iron should be avoided for this purpose. The settler may be made as large or larger than the digester. 3. An evaporating pan (iron, heated by steam or fire). 4. Coolers, mostly made of wood, but I recommend them to be made of flags or slate, or, better still, one large shallow slate or flag cooler. 5. A drainer for "draining" the salts, made of wood, and of any shape. 6. A stove for drying the salt, formed of wooden shelves any width, and about eighteen inches apart, heated by means of steam passed through pipes along the floor of the stove. 7. A washer for washing the "settlings" of the settler. 8. A steam boiler.

This may be considered the whole of the plant. And now, supposing we have a digester—say, about six feet square and seven feet deep—we commence by placing, say, three tons of magnesian limestone in the digester. We then add the acid—say, twelve ordinary carboys. Now turn in the water till the mixture has a specific gravity of 1125 or 1150. Allow the acid and water to act upon the stone for an hour or so, then turn in the steam, which is supplied by the boiler. A lead pipe of about three quarters of an inch bore is made to go about halfway down the digester, and through this the steam is forced into the liquor. From eight to twelve hours is the time taken to neutralise a "batch."

When sufficiently neutral, the liquor in the digester will stand from 40° to 50° on Twaddell's hydrometer. It is then run off by means of a tap or plug into the "settler." If the liquor happens to show a trace of acid, it is neutralised, and any iron present precipitated by any of the known means. It usually takes three or four hours to "settle." It is then siphoned off into the evaporating pan. The same routine above mentioned is worked over again until sufficient liquor has been obtained for a "boiling;" care is always taken to keep the liquor free from acid—indeed, working on the alkaline test may be said to answer best. The liquor in the boiling-down pan is evaporated till it stands, say, 66° or so by Twaddell. When this point is reached, the steam (if used) is turned off, and the liquor is allowed to remain undisturbed for a few hours, so as to allow all floating particles to settle down. Care is taken that the liquor is very clear before it is run off. When sufficiently settled it is run off into the cooler or coolers, and agitated at stated intervals to make the salt fall in small crystals. When the salt has finished falling, the mother liquid is run off and pumped into the evaporating pan; New liquor from the digester is added, and the same process as already described is gone over again. The salt is taken from the coolers and allowed to drain. It is then placed on the shelves of the stove and dried; the heat of the stove ought not to exceed 80°. When sufficiently dried it is sifted, sometimes crushed, and packed in casks. The settlings from the "settler" are placed in the "washer" and washed, and the liquor is allowed to filter through, when it is pumped into the evaporating pan along with the other liquor.

This may be said to be the whole process. Of course, the object to be aimed at in making sulphate of magnesia is purity and freedom from iron, &c. When iron is present it is easily detected by bisulphohydride of ammonia or by yellow or red prussiate of potash, &c. When used by warp-sizers, it can only be said to add weight. If such salts are to be used, there is no doubt that chloride of barium will in time take the place of Epsoms for sizing purposes. Chloride of barium is much better for this purpose than Epsoms, and by the use of it the cloth is not so liable to mildew; indeed, it acts in the manner of a preventive against that much-heard-of complaint. But it must be understood that a greater weight is added to cloth in the manufacture of which chloride of barium has been used. The injury to cloth —and much has been said on this point—results chiefly from the amount of moisture, &c., which is introduced by the use of various salts. We know that water enters largely into the composition of Epsoms—51·21 per cent. being water; whereas, in chloride of barium, we have only 14·77 per cent. of water, with a specific gravity of 3·049. From this comparison many obvious conclusions may be drawn. The quantity of sulphate of magnesia made yearly may be placed at upwards of 12,000 tons.

PHARMACY, TOXICOLOGY, &c.

The New Pharmacopœia (1867).

[SECOND NOTICE.]

THE book, as yet, is not available for ordinary readers, and so we reserve special remarks upon manufacturing chemical processes till we have full space to note such specialities, and when the text-book can be referred to in support of any statements that may be made. We will, therefore, at present content ourselves with giving the general broad outlines of the book, and when we have done this our readers will be prepared to follow with us the specialities in more detail.

It is well known that our most scientific chemists have taken great interest in the present edition; this was shown by the memorial presented to the Medical Council by the Council of the Chemical Society. The object of this memorial was to urge the omission of all chemical formulæ from the new edition, chiefly on account of the transitionary state of this part of chemistry. This advice seemed sound, but the only other alternative that presented itself has in preference been adopted. Symbols by the older authorities are given in ordinary capitals, and those of the *new system* in thick Egyptian type.

A commentator on this remarks:—"It possesses evident advantage over the method of barred symbols adopted by some authors. The presence of the bar gives a needless appearance of complexity to a formula." The author of this criticism must be in happy ignorance of the depth of profundity to which chemical formulæ have now attained.

The Council, then, in neglecting what may be called expert advice, have assuredly made a grievous error. It is, indeed, melancholy for a committee to write down one old and one new formula, in happy ignorance that there are several old systems of notation and quite half a dozen new ones. Nothing but confusion could possibly come from such policy. Supposing even that *a* new system of notation were adopted, it would have been wise to burden the minds of those seeking knowledge by an empirical formula only; but chemists will be astonished to learn that with new symbols rational formulæ also are given. We give a few examples of the new symbols. Acetic acid is described as follows:—"100 parts by weight contain 33 parts of acetic acid $HO.C_4H_3O_3$ or $\mathbf{HC_2H_3O_2}$, corresponding to 28 parts of anhydrous acetic acid $C_4H_3O_3$ or $\mathbf{C_4H_6O_3}$." This information is either just too much, or, as we think, just too little. To a student nothing could look more similar than the two formulæ given in an old notation—nothing

more dissimilar than the corresponding ones of the new, as given in the text. Of course, the student may choose whichever of the two sets of symbols given he pleases, as long as he is consistent; no one could fairly expect him to know both. But, bad as his case may be, we pity the Materia Medica examiner still more.

By the new chemistry of the Pharmacopœia it is stated that calomel (by the way, altered to the subchloride of mercury) is written $HgCl$, and alum is given as $NH_4Al(SO_4)_2.12H_2O$. Will any one doubt, after these typical examples, the soundness of the advice given by the Council of the Chemical Society?

It is our duty to mention these defects, but we may say that such a criticism is forced upon us by the contrast that is afforded by the general sound treatment of these delicate subjects. The weights and measures are remarkably well treated, and will give dissatisfaction to no one—indeed, we think that the system, as modified by the Committee, will be felt to be a boon by practical chemists who may wish to express any results readily transferred from our own weights to those of the metric system. It will also afford a transition by which the latter may be more gradually and conveniently brought into use. The subject might have been made of equal difficulty with that of chemical symbols, but it is satisfactory to find that two systems are not given as a further means of confusion.

The measure has been replaced by a grain measure in which the weighing of any reagent used for volumetric analyses is necessary. For this purpose, flasks, such as are ordinarily used, are recommended for weighing; thus, in the direction for preparing a weak acid, it is recommended to *weigh x* grains of the strong acid, and then to add distilled water until the mixture after being shaken reaches the mark graduated on the neck of the flask. The old inaccurate measures are thus dispensed with, and this very simple plan, requiring only a little more care, will insure a uniformity hitherto practically unattainable by the ordinary pharmacist. The metric system is not introduced into the body of the work, but its use has been sanctioned in the appendices for volumetric analysis. A grain measure is the volume of a grain of water. In the former edition an arbitrary measure of 10 grains was used, and was called the measure; thus in the directions we formerly read, take of such a liquid *x* measures—*i.e.*, 10-grain measures; but now we should read instead the number of 1-grain measures required.

A cubic centimetre is the volume of a gramme of water; therefore, the relation being the same with that of the grain and the 1-grain measure, the analyst may either neutralise 75 *grains* of tartaric acid by 1000 *grain measures* of the volumetric solution of soda, or 75 *grammes* of the same acid by 1000 *cubic centimetres* of the alkaline standard solution, or still more easily, as far as conveniency of bulk in some cases requires, take 7·5 grammes of the acid with 100 c.c. of the soda solution very readily.

This simple abolition of the arbitrary measure has cleared away all the clumsiness and confusion of the last edition, and those only who have read carefully the preparations for the solutions formerly given can fairly judge of the importance of a slight alteration such as this. This process of weighing in graduated flasks, as replacing measures formerly given, is the only alteration made in this department of pharmacy.

In many cases permissive processes are given for the preparation of various substances where there are two or three equally good ones. This holds in the cases of the preparation of atropia, sulphate of quinine, and others; but for hydrocyanic acid, ether, and others, only one process is given. It will be remembered that the last Pharmacopœia was very exhaustive in its description of preparations, so much so that one would judge superficially that it was the best plan to make everything for oneself and ignore the manufacturing chemist altogether, who of course can prepare a chemical body in a state of purity by a wholesale process at a far cheaper rate. By a deeper study of these preparations, however, a case like the following may occur:—For the preparation of pure nitrate of silver for volumetric purposes, take of pure silver, so much. One then turns to silver, in another part of the book, to find how pure silver is obtained: the direction is—Take of pure nitrate of silver, so much. So an interesting circle is described, and the reader is left in doubt as to whether pure silver or pure nitrate of silver exists in nature or not, and if so, which of the two.

The methods ordinarily used by wholesale manufacturing chemists are now in almost every case stamped with authority, more than one in many cases being so allowed; and this deference to better authorities as regards practicable methods of chemical manufacture is very well timed and in the best taste.

(To be continued.)

FOREIGN SCIENCE.

(From our own Correspondent.)

Paris, April 10, 1867.

M. Humbert de Molard presented to the French Photographical Society, at the last meeting, a new instantaneous shutter for photographic cameras, which allows the following problem to be resolved: Given several object glasses, to take on a single plate, in a fraction of a second, as many proofs as there are object glasses, not by uncovering them all at once in the same moment, but one after the other, so that a living person can be represented in the different phases of the movement which takes place in the part of a second for the use of the phenakistoscope. The instrument is composed of a sort of frame set up in front of the object glasses, and pierced with as many holes as there are lenses. The light is excluded by an opaque curtain stretched in the same way as carriage screens, which can exclude the light either instantaneously or at any slowness desirable. The openings are so disposed in the opaque curtain as that, by the movement of ascension, the first coinciding with the first row of objectives, unmasks successively each of the lenses, while the others are screened and the light excluded. The second and the third openings, placed at proper distances, coincide in their turn with the second and third rows of lenses, and expose them successively in the same way as the first aperture. Thus can be obtained, during the time that the curtain takes to extend itself, the twelve or sixteen successive proofs which the phenakistoscope requires to produce a sensation of movement.

The *Moniteur* of the 5th inst. mentions the following meteorological event in terms which appear to have been paid for by the coal and charcoal sellers of Paris. "The '*lune rousse*' commences to-day, April 4. This moon is distinguished by the protracted frosts which are produced while it shines above the horizon. It has not failed in its general routine of habitual programme. The day has been colder than the preceding, and it was only in the afternoon that, after a lengthened drizzly rain, the atmosphere was a little warmed." This audacious assertion has some connexion with those on lunar influence propounded in England by Mr. Harrison, &c.

M. Dubrunfaut, director of the experiments on the cultivation of beetroot by chemical manures, has blamed the operators with having made the comparisons based upon the actual weight of the roots, and not upon the saccharine quality of the same. M. Denoyon, in his name and in that of M. Levy, hastened to respond to this objection, which happily was without foundation. The roots, having given under the influence of chemical manure 60 tons per hectare, furnished more syrup at the first squeezing, and gave 2 per cent. more sugar, than that of beetroots cultivated without chemical manure. Moreover, the molasses of the second squeezing furnished 41 per cent. per hectolitre instead of 40, the amount obtained with the beetroot cultivated with ordinary manures.

At the last meeting of the Academy of Sciences Baron Seguier called attention to a new gun, constructed by a clever gunsmith, M. Galand, who had the fortunate idea of inflaming the cartridge by the summit, and to make the gases act upon the projectile by the intervention of a compressible body, so as to overcome its inertia without shock, as if by a spring successively stretched, which in shrinking renders all the force stored up within it. In the new arm M. Galand fixes a copper cap at the end of a screw acting as a breech. This many-filleted screw enters the chamber sufficiently to form a solid and sure resisting piece. The arm is opened by a slight movement of the hand, and, at the moment of discharge, the copper cap, being very malleable, opens out at the instant of the explosion by the pressure of the gases. The same screw which acts as breech, when unscrewed, easily draws out the copper cap which has been flattened out into the conical space in which it enters at each manœuvre. It is in part hollow, and contains the four pieces of mechanism for percussion of an extreme simplicity. The needle which ignites the charge acts as a detent, a kind of hook replacing the head of the hammer in the action of cocking. To take all the mechanism to pieces, it is only necessary to unscrew a simple bolt. This new firearm costs at most 1*l*. Its form, compared with that of the ancient arms, is rather singular; there being no detent, there can be no accidents. To determine the explosion the pallet inserted into the body of the screw must be pressed by the thumb. The cartridge consists of a small cotton bag, having at its extremity a disc of cotton furnished at its centre with a small quantity of fulminating powder. Five grammes of powder are poured into the bag, a greased wad separates the powder from the ball, and the bag is tied with a ligature. The cartridge leaves no residue whatever after firing. The principal dimensions of the Galand gun are :—Diameter of barrel 10 centimetres; pitch of grooves 1 turn in 75 centimetres of the barrel; weight of ball 26 grammes; charge of powder 5 grammes. The ball penetrates a deal plank at the distance of a thousand metres.

The Duc de Luynes, whose inexhaustible generosity is known and admired by all the world, as far as relates to the sciences and arts, placed at the disposal of the French Photographic Society a sum of 10,000 fr. (400*l*.) as a prize for researches made upon the causes of the alteration of photographic proofs, and the discovery of a method of printing these same in carbon, or some sort of ink that will be indefinitely unalterable. Already in 1859 the Society divided amongst several competitors, MM. Poitevin, Davanne and Girard, Pouncey, Garnier and Salmon, a first sum of 2000 fr. (80*l*.); the Society also named April 1 for the decisive award of the rest of the money, 320*l*., for the complete resolution of the problem theoretically, and the practical application of a process capable of resolving the difficult problem of the application of it in printing positives in unalterable ink. Hindered by some unknown cause, the commission named to decide upon the merits of the works sent in for competition at length reported at the last meeting of the Society, Friday, April 5, and awarded the whole of the 320*l*. to M. Poitevin, who, in 1855, was the first to discover and to apply completely and practically with advantage, a process by which objects are transferred to stone, and printed off in any quantity in a lithographic press. M. Poitevin had many illustrious competitors—MM. Ch. Nègre, Nièpce de St. Victor, Lemercier, Salmon and Garnier, Rousseau, Placet, Baldus, &c.; also the English labourers in the field—Talbot, Pouncey, Pretsch, Woodbury, Colonel Sir Henry James, &c.; but in a very important and profound discussion, the reporter, M. Davanne, the organ of the commission, the judge of the competition, proved that the palm was due to M. Poitevin, a man at the same time eminent and modest, who always aims in photography at arriving towards the perfection of unalterable proofs. It is true that M. Poitevin has been greatly aided by the co-operation of M. Lemercier, the celebrated lithographer, though he was equalled or exceeded since the closing of the competition by MM. Gainset, Baldus, Tessié de Mothay, and Maréchal de Metz, but the merit of his invention gives him the pre-eminence which the commission had so justly attributed to him. We may add that MM. Tessié de Mothay and Maréchal purchased the patents of M. Poitevin, taken out in 1855, for 400*l*. Less than a year ago he was obliged to support his family by accepting the humble situation of chemist in a small town, Ahun, in the department of the Creuse. Fortune has since favoured him.

Some months past a very ingenious man, M. Lavater, begged us to put him in communication with a skilful chemist or photographer who would help him to develope and bring to success an incompleted method for copying commercial letters and others by aid of a dry process. Every one understands what immense interest is attached to the subject of being able to reproduce a letter or manuscript by the simple application, with pressure, of a dry paper on the original. No one, we thought, could be better prepared on this subject than M. Nièpce de St. Victor for the solution of this difficult problem. So we sent M. Lavater to him. He set to work immediately, but without success; the dry method was continually unable to succeed, and it had to be laid aside for the present. The wet process, very troublesome and limited in its actual mode of application, gives only one copy—and a very imperfect one—of the writing to be reproduced. We are happy to learn that MM. Nièpce de St. Victor and Lavater have now substituted a method as easy as it is practicable, in the sense that it gives a great number of copies even after the original has been written for several weeks. The copying paper is to be slightly wetted with a sponge, and placed upon the original; it is then submitted to the vapour of a certain liquid easily procured; the writing on the copy, hardly visible, and at times quite invisible, appears at once fixed completely. The operation can be carried on the following days; and at a future period, not far distant, we shall give the composition of the developing fluid. It is necessary that this sort of ink should either contain gallic acid or logwood.

M. Claud Collas, a celebrated apothecary of the Rue Dauphine, continues his researches on the phosphates in general, and in particular the phosphate of lime, the powerful auxiliary of animal and vegetable life, and the activity of which continues in force even after death, but in a contrary sense. M. Collas has, in fact, demonstrated that the phosphate of lime becomes a decomposing agent of putrefaction, and after death hastens the dissolution it was the means of preventing during life; it also favours the development of new existences. Observation proves that in pregnant women or wetnurses there is an absence of phosphate of lime in the organism and the presence in the urine of sugar. The phosphate passes in a great part into the blood and into the milk, so as to serve for the consolidation of the bones of the infant, which are at birth in a cartilaginous state. M. Collas advises the following preparations :—1. *Solution of phosphate of soda*—namely, 8 grammes of phosphate in spring water. It is to be taken instead of mineral waters, mixed with wine, and at the

rate of two or three glasses per day. 2. *Phosphoric lemonade*—phosphoric acid 2 grammes in a litre of spring water, taken from time to time as a beverage. 3. *Hydrated phosphate of lime milk*—ordinary hydrated phosphate of lime 50 grammes, water 100 grammes, mixed together in a mortar, and then passed through a strainer or fine sieve; one, two, or three spoonfuls to be taken daily, especially in soup. This is the best way of administering phosphate of lime to rickety children. The phosphate of soda has the property of converting sugar into glucose in presence of carbonic acid. Cannot we attribute the viscous fermentations which sometimes appear in the distillations of beetroot juice to the presence in the juice of an excess of soluble phosphates and carbonic acid, in considering them as a first degree of disorganisation, caused partially by the phosphates?

A very ingenious young man, M. Maiche, jun., Rue Turenne No. 46, has made a considerable improvement in the manufacture of starch, which gives a greater return and will be necessarily adopted in all factories of that article. It consists in a new method of sifting the impure starches obtained by the known processes. If we take a sieve, the tissue of which is close enough not to let the grains of starch pass, these latter are deposited on the cloth of the sieve, and the sifting proceeds only drop by drop—that is to say, it is practically impossible. But if, instead of pouring upon the strainer the water charged with starch, we place the strainer on the water itself, agitating it by striking the edge, the starch passes upwards with the water, while the foreign substances remain at bottom. The mechanism for this purpose is composed of—1. A wooden case. 2. Another case of smaller diameter, the bottom of which consists of a layer of silk, and which is inserted into the former. 3. A ratchet wheel, the axle of which rests on two bearings fixed on the edge of the great tub. This wheel serves to give the sifting vessel a shaking or jumping motion. A tube of india-rubber conducts the impure starch into the tub. Another tube, siphon-shaped, takes off the water charged with starch which has passed through the sieve. Twenty-three kilogs. of impure starch give 20 kilogs. of pure starch, worth 16 fr., instead of 5 fr. 75 c. This gives, in favour of the new process, 51 fr. 25 c. per 100 kilogs. The process has been installed in a factory at Lurey, in the Haute-Saône, where it is expected to give from 10,000 to 20,000 fr. net profit.

F. Moigno.

THE PARIS EXHIBITION.

(From a Correspondent.)

Dirt, disorder, packing-cases, dust, and noise, reign supreme throughout the greater part of the building where those products specially interesting to your readers are located. It is quite impossible, and will be for many weeks to come, for me to send you any connected account of the chemical section. The English department is certainly nearer completion than the rest of the world; indeed, most of the cases are up and filled, but many of the most striking objects are covered over to protect them from the inevitable damage they would receive if exposed to the adverse influences which reign around.

I would not advise any of your readers to come here before the end of May, as it is quite impossible for the building to have put on its holiday attire before that time. It is true that the hot season will then be close upon us (and all *habitués* of Paris know what that means), but chemists are accustomed to furnace operations, and as the most gloomy imaginations have not predicted a higher temperature for the interior of the building than 50° C., your readers, especially those engaged in the glass and iron manufacture, will not feel this any detriment. Besides, have we not elaborate systems of ventilation, which are to be in full force, drawing the heated air out of one court into another, and wafting it about the building?

At present I cannot give an account of anything *seriatim*, but must content myself with picking up such novelties here and there as may be likely to interest you. Perhaps the most striking object in the metallurgical department, Class 40, is the magnificent case, the size of a small room, with its costly contents, exhibited by the firm of Johnson and Matthey, Hatton Garden, London. They show platinum stills and siphons capable of concentrating eight tons of oil of vitriol per day. These are remarkable in many respects. The metal of which they are made is said to be of chemical purity, and the joinings are not soldered together with gold, as in the usual way, but the two edges of the metal are actually melted together before the oxyhydrogen blowpipe, so that the whole apparatus consists of only one piece of metal. It is thus rendered much stronger, more durable, and cheaper than those made by the old plan. Amongst other articles of platinum in this case may be noticed ingots and bars of platinum fused by Deville and Debray's process; platinum alembics for use in parting gold and silver; platinum tubes, soldered by the autogenous process; platinum wire, sheet, foil, leaf, crucibles, capsules, sponge, granulated and native; touchholes for cannon made of fused alloy of platinum and iridium; one of those exhibited has been used in a Whitworth gun for more than 3000 rounds, and scarcely shows signs of wear yet. Those who know the constant trouble and expense which are occasioned by the wearing of the vent-pieces of cannon when in active service, will appreciate this important adaptation of Messrs. Johnson and Matthey.

One very important and instructive series exhibited by this enterprising firm is a collection of noble, rare, and common metals, of chemical purity, and cast into symmetrical form to illustrate practically their specific gravity and characteristic appearance in the fused state. The ingots weigh one kilogramme each, and consist of gold, silver, platinum, iridium, rhodium, palladium, lead, bismuth, copper, cadmium, cobalt, nickel, iron, antimony, zinc, magnesium, aluminium, thallium, sodium, and potassium. Besides these are osmium in the pulverulent state, and mercury. This series is in the highest degree instructive, and even those who are well acquainted in detail with the metals composing it, can have no idea of the vivid manner in which their properties of weight and colour impress themselves on the mind when presented in this eminently glyptic manner. The wonderful density of iridium and platinum is in striking contrast to the levity of magnesium, sodium, and potassium. I cannot help regretting that the series is not closed with lithium; the bar of this metal would have been upwards of three times the length of the magnesium. Thallium stands in about the centre of the series, being very close to palladium.

In addition to the masses of platinum, this firm exhibits an accurate model of the enormous ingot of platinum, weighing 100 kilogrammes, or one-eighth of a ton, which attracted so much attention in 1862.

The value of the precious metals shown by Messrs. Johnson and Matthey is about half a million francs.

The same firm also exhibits specimens of sodium amalgam, which is now so largely used for the extraction of gold from its ore. The results of carefully conducted experiments are shown side by side. They are truly astonishing. The mineral chosen was a composite Californian one, which had been found very difficult to work by the ordinary process. The results obtained by Messrs. Johnson and Matthey were the following:—

	Grammes.	Ounces.	Dwts.	Grs.	
Product by the ordinary method of amalgamation	87 =	2	16	0	per ton.
Product by the sodium process of Mr. Crookes	218 =	7	0	6	,,
Given by assay	232 =	7	9	0	,,

The experiments were twice repeated, and the results were absolutely identical. It is not unlikely that later in the season an opportunity will be given of illustrating the advantages of this process on a large scale in one of the laboratories in the adjacent park.

Among the great industrial inventions shown in another part of the building I may remark the process by which M. Mond, a chemist of Utrecht, extracts sulphur from soda waste without removing it from the vessels containing it. This process consists in forcing a current of air into the waste in order to oxidise it, after which a stream of water is directed upon it so as to lixiviate it. The mixture is then subjected to another similar treatment, so as to concentrate it, after an interval which varies from sixty to seventy-two hours. In order that the sulphur may be regenerated as much as possible, the oxidation must be regulated so that the liquors contain two equivalents of sulphide of calcium for one of hyposulphite of soda. The solution is then transferred to vessels either of wood or refractory brick, and an equivalent of chlorhydric acid is added. The sulphur is at once precipitated in a state of purity, without any perceptible disengagement of sulphuretted hydrogen gas or sulphurous acid. If, instead of chlorhydric acid, the residues of the chemical works for the fabrication of chlorine (a mixture of chloride of magnesium, perchloride of iron, chlorhydric acid, and free chlorine), the oxidation of the liquors may be so modified that they contain very little hyposulphite. He also adds a peculiar preparation to the mixture above described, in necessary and sufficient proportions to neutralise the free chlorhydric acid and reduce the protochloride and perchloride of iron. A precipitate is thus obtained containing 95 per cent. of sulphur. In chemical works in which chlorhydric acid is advantageously employed, the lixivia are superoxidised, so that they contain enough hyposulphite to be easily separated into sulphur and sulphate with very little sulphurous acid. The sulphur thus obtained is mixed in a quantity less than a third with sulphate of lime, and should be purified. Treated by this process the soda waste contains very little sulphide, but much carbonate and sulphate of lime. Far from being injurious, the latter are very serviceable as ingredients of chemical manures. The expense is inconsiderable, the cost of the apparatus being covered by the first year's crop, and the net profit of the regeneration, and for an establishment producing 3 tons of soda per day, will be at least 400*l.* per annum.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, April 4.

WARREN DE LA RUE, *Esq., Ph.D., F.R.S., President, in the Chair.*

THE minutes of the anniversary meeting and of the last ordinary meeting were read and confirmed, and several donations to the library were announced. Messrs. F. S. Barff, M.A., and Alfred Tribe were formally admitted Fellows of the Society, and the following gentlemen were duly elected—viz., Mr. John Mackay, 119, George Street, Edinburgh, and Mr. David Skinner Kemp, Bombay. For the second time were read the names of Alfred Coleman, Plough Court, Lombard Street, and William Phipson Beale, barrister-at-law, Stone Buildings, Lincoln's Inn. The candidates proposed were William Gowland and George Robert Gowland, both of 48, High Street, Sheffield; John C. Brough, journalist, 4, Norman Terrace, Stockwell; Edward Packard, Jun., manufacturing agricultural chemist, Ipswich; F. W. Peterson, of her Majesty's Mint, Calcutta, 51, Myddelton Square, London.

Dr. J. H. GLADSTONE made a short statement respecting the "solidified glycerine" which was exhibited by Dr. W. S. Squire on a recent occasion. It was then said to be a task of great difficulty to procure again the white crystals from a liquefied portion of the substance in question, but the speaker did not find it to be so, for a sample which Dr. Squire kindly permitted him to take from that shown at the meeting a fortnight since was placed (in a bottle) on a warm mantelpiece, where it soon became perfectly fluid, but on being removed only to another part of the room, the crystals were formed again in it the next morning. Snow had fallen during the night, but the frost was by no means severe, and even now, after a week of mild weather, a portion of the glycerine was yet solid. (The bottle, with its contents partly crystallised, was handed round for inspection.)

A paper, entitled "*Experiments on Oxidation by means of Charcoal*," by Dr. F. CRACE CALVERT, was read by the SECRETARY. After referring to the early experiments of Theodore de Saussure, and those of ten years ago by Dr. Stenhouse, the author proceeded to inquire into the *modus operandi* of the absorption of gases by charcoal—whether, for instance, in the case of ammonia, this substance existed unchanged, but in a state of great condensation, within the pores of the charcoal; or whether it underwent oxidation, and so became destroyed by the exalted affinities of the oxygen or air compressed within the charcoal. This problem is not solved, but the author considers that there is evidence of the destruction of ammonia when this gas is mixed with oxygen and placed in contact with charcoal, but whether nitric acid is formed, or only nitrogen and water, is left open to further investigation. Sulphurous acid and gaseous sulphide of hydrogen were very soon oxidised, and converted into sulphuric acid; so also phosphoretted hydrogen quickly became phosphoric acid. Alcohol vapour diffused in oxygen was changed into acetic acid, and methylic alcohol is believed to be converted into formic acid. Amylic alcohol furnished valerianic acid. Ethylene, propylene, and amylene were then experimented upon in a similar manner; all of them produced carbonic acid and certain residual oxides, but the latter were not distinctly identified. The author concludes by advancing a speculation to account for the phenomena observed by him, and suggests that possibly the condensation of oxygen and other gases by charcoal amounts to an actual liquefaction within its pores, and by thus being brought into closer contact, the bodies are respectively placed within the sphere of each other's attraction, and a chemical change occurs accordingly.

The PRESIDENT, in moving a vote of thanks, referred to the difficulty sometimes encountered in accurately defining the physical condition of bodies; thus, in the operation of coining, and particularly in the manufacture of tin capsules, the solid metal behaved almost like a fluid substance, and the particles appeared so mobile that they might almost be compared to a veritable liquid. At an early hour the President suggested an adjournment for the purpose of enabling the Fellows to attend the meeting of the Royal Society, at which a paper of great chemical interest, "*On the Stability of Gun-cotton*," by Mr. F. A. Abel, was then being read.

PHARMACEUTICAL SOCIETY.

April 3, 1867.

G. W. SANDFORD, *Esq., President, in the Chair.*

MR. HANBURY laid several botanical specimens on the table for the Society to select any they might wish to have for the museum.

Mr. A. F. HASELDEN, before continuing his paper "*On the Codex and the British Pharmacopœia* (1864) *Compared*," said there was a slight error on the title-page of the *Journal*; instead of the British Pharmacopœia, 1867, it should have been 1864. At the last meeting the author said that he had undertaken a work of no small labour

and magnitude, and in one paper he knew it to be impossible to go fully into the subject, but his desire was first to notice the report and preface, and then to take each part separately and point out any difference he thought worthy of notice between the Codex and the British Pharmacopœia. The work contains a report to the Emperor, a preface, preliminary remarks, Materia Medica, and the Pharmacopœia. Under preliminary remarks, weights and measures are noticed. As it is now compulsory in France to use, in weighing or measuring, the decimal-metric system, the Codex contains four tables relating to weights, the only measure in use being the litre and the decimal divisions thereof. The author then referred to the table which is given in the Codex, showing the value by weight of spoonfuls, glassfuls, handfuls, and pinches, remarking that the British Pharmacopœia contained no such table, and that it would be to us a retrograde movement, pinches and handfuls being only employed in the kitchen. For certain liquids the compilers of the Codex have recommended the use of a *compte-gouttes*, which consists of a globular glass bottle with a lateral tube, the interior diameter adjusted so as to allow a liquid to flow drop by drop. Mr. Haselden showed various kinds of drop measures which had been invented, but he could measure as accurately and quickly as necessary with the minim measure. The *compte-gouttes* might be useful to patients taking any particular medicine by drops, but the system of drops, either in prescribing or administering medicines, should be discontinued, prescribers writing minims instead of drops, and administering nothing less than a teaspoonful. The author then referred to that part of the Codex relating to densities and areometers or hydrometers, saying that Beaumé's was the one directed to be used. He then passed on to the Materia Medica, the first section of which comprises those substances which are obtained either from the vegetable or animal kingdom. Amongst the animals named were the vine-snail, cellar-woodlouse, viper, frogs, &c. The author pointed out that in both books the arrangement is alphabetical. The Codex contains nearly double the number of substances that are in the British Pharmacopœia. In the Codex the common name is given in French, the botanical in Latin, the order or sub-order and the part to be used in French. Mr. Haselden then proceeded to notice some of the substances contained in the Materia Medica, comparing them with the British Pharmacopœia. The root and leaf of aconite are employed, but, as the root is more active than the leaf, the pharmaceutist is directed to use the preparations from the leaves if the tincture or extract of the root is not specified. Three kinds of aloes are named, the preference being given to Cape. The root and leaves of belladonna are directed to be employed, but nothing is said about the state of the leaf. Mr. Haselden showed some specimens of benzoin, dried jujubes, &c., and noticed catechu, cascarilla, colchicum, coriander, cubebs, hyoscyamus, taraxacum, &c. He concluded his paper by saying that if his friends had not given him the opportunity of spending a short time in France and acquiring a knowledge of the French language he would not have had the pleasure of meeting them that evening to notice the differences between the two Pharmacopœias.

Mr. Joseph Ince read a paper "*On the Theory of the Universal Codex*," in which he stated that he believed it was perfectly impossible to assimilate the whole of the Pharmacopœias. The British Pharmacopœia was specifically English; viewed in every light it was British; and the Codex was a French book only adapted to the French people. Mr. Ince referred to some of the preparations to show how useless they would be in other parts of the world. In concluding his paper, he advocated the decimal-metric system of weights and measures, and regretted that the Pharmacopœias were not written in Latin.

Dr. Farre fully endorsed every word Mr. Ince had said. It was found very difficult to construct the British Pharmacopœia, and he believed it would be impossible to construct a universal Pharmacopœia.

Dr. Attfield thought it quite possible to form a basis for a universal Pharmacopœia. He hoped they would be able to discuss the subject at the Paris conference in August.

Mr. Squire wished to direct attention to a rule adopted in the Codex which he thought was a step in the right direction. The strength of the tinctures in most cases was one in five or one in ten, while in the British they differed very much.

Dr. Redwood thought the subject of constructing a universal Pharmacopœia worthy of consideration. The Indian Pharmacopœia had hitherto very much resembled the London Pharmacopœia. He was aware that a new one was in preparation, and he would like to hear from Mr. Hanbury, who, he believed, was engaged in the work, in what points it would differ from the former editions.

Mr. Hanbury said the new Indian Pharmacopœia would contain all the medicinal plants, &c., found in India; it would partake more of the character of a dispensatory, and was intended to be used as a text-book in the Medical Colleges. With regard to Mr. Ince's paper, Mr. Hanbury thought it not impossible to assimilate the Pharmacopœias; there would be far less difficulty with the German Pharmacopœia than the French Codex. Since 1788 our own Pharmacopœia had gradually become more simple.

Mr. Deane drew the attention of the meeting to a new stove for pharmaceutical purposes, which he had found more useful than the pharmaceutical stoves in general use.

The Chairman announced that this was the last meeting of the session. He thanked those gentlemen who had favoured them with papers, and said that a *conversazione* would take place on May 14.

ACADEMY OF SCIENCES.

April 8, 1867.

(From our own Correspondent.)

M. Dupré, of Rennes, presented the description of a machine by the aid of which he makes, without integration, the calculations relative to different applications of the mechanic theory of heat.

M. Chevreul announced the distribution of the twenty-ninth volume of the *Mémoires* of the Academy, wholly occupied with M. Delaunay's theory of the moon.

M. de Quatrefages presented the volume entitled "The Seasons, Studies of Nature," which M. Ferdinand Hoefer has just published through Hachette and Co.

M. Velpeau presented, in the name of the celebrated surgeon, M. Simpson, the description of his steel-suture process, with numerous observations, and operations crowned with complete success. This process, which advantageously replaces the caustic of the ancients or the ligature of Ambrose Paré, consists in implanting under the artery, in contact with it, a needle, on which it presses sufficiently to stop the pulsations.

M. Dumas announced the news of the production, artificially, by M. Wurtz, of a considerable number of alcohols from the series creosote, phenol, &c. M. Wurtz treats the substances—carbolic acid, for example—first by anhydrous sulphuric acid; potash does not then regenerate the body, but it gives rise to the corresponding alcohol, creosote, or phenol. The celebrated Belgian chemist, M. Kékulé, has succeeded in obtaining similar reactions, which he will shortly publish.

We recommend to our readers the interesting and courageous work that Dr. Blutin has published through Hachette and Co., entitled "Our Cruelties towards Animals, to the Detriment of Health, Public Prosperity, and Morality."

M. Marié Davy requested the examination by a commission of a memoir on the electrometric force, which he measures by the aid of a thermometric heating apparatus of particular form.

NOTICES OF BOOKS.

An Essay on Dew, and several Appearances connected with it. By William Charles Wells. Edited, with Annotations, by L. P. Casella, F.R.A.S.; and an Appendix by R. Strachan, F.M.S. London. 1866.

We think Mr. Casella has rendered good service to scientific literature by the republication of Dr. Wells's celebrated essay, which has been out of print during upwards of forty years. This essay has been praised in such very high terms by Sir John Herschel, John Stuart Mill, and other writers down to our own day, that access to the work is desirable on many grounds. Mr. Casella repeats the substance of the praise in his own words:—"The essay, as a literary production, is a model worthy the attentive study of scientific experimentalists and students" (p. iii.); and yet at p. v. it is admitted that "all the main facts and features of the theory were known beforehand;" and further, "that he (Wells) insufficiently acknowledged the labours of his predecessors may be admitted." Is it meant that when the student writes a paper on his own account, and takes this essay as his model, he is not to acknowledge the labours of his predecessors?

The fact is, there are two classes of scientific men—namely, *workers* and *writers*—and the two are not often combined. The worker, in writing his own memoir, is generally too intent on his own share in discovery to do more than accept the conditions of the question in hand from some writer who himself may perhaps have compiled from earlier books, and not have taken the trouble to consult original memoirs. There are not many writers who work at scientific literature with the same zeal with which literary men pursue their labours, and the reason is to be found in the marked difference between literature and science. A literary work bears the impress of *mind;* a scientific work bears the stamp of *nature*. The one is individual and proper to the man; the other is general and has no individuality. A work by Shakspeare remains for all time untouched, unchanged; a work by Davy may be taken up by Faraday, and Faraday's work may be carried on by any number of his contemporaries or successors. And this is probably what Lord Bacon meant when he said that his method of philosophising tended rather "to level wit and intellect." "For as in the drawing of a straight line or accurate circle by the hand, much depends on its steadiness and practice; but if a ruler or compass be employed, there is little occasion for either; so it is with our method." It is on account of this absence of individuality in scientific writing that we have so few good scientific writers. Our scientific style is often slovenly, or, what is worse, is afflicted with that vice of inexperience—namely, *fine writing*. And here we may refer with admiration to the charming simplicity of style in Dr. Wells's essay, and in this respect we certainly admit that it deserves to be a model. The scientific writing of the French deserves similar praise, but the French have a better scientific training than we can give; moreover, they are more logical than we; they are proud of their language, and more critical in the use of it.

The interest that is felt in literary history, as compared with the comparative want of interest in scientific history, rests on the fact that a Chaucer, a Shakspeare, a Dryden, a Gibbon, is each an intellect rounded, complete, and final. But, without meaning the slightest disrespect to such great men as Newton, Davy, Faraday, it must be admitted that they are but parts of a great whole, and that whole is Nature. We care more about the laws of nature than about their discoverers; but every one feels an interest in a great writer, because he and his works are inseparably connected. An unpublished letter by Goldsmith, a few unpublished lines by Dryden or Pope, would excite the ardour of our whole literary world. A new fact in the history of oxygen, or of the composition of water, would fail to receive more than a passing glance from scientific men. They consider that all the main facts are embodied in text-books, handbooks, and other treatises, while that which is not embodied is of no consequence. They consider that we have the discoverers and the dates of all important facts, in the main, correct. They want to pursue discovery, not its history, and hence they feel but little interest in the light thrown by old memoirs on the progress of the past.

When, however, we meet with a writer like Dr. Whewell, who knows his business and gets a true impression by tracing the history of a theory or of a discovery down to the time when it receives its last touches, we accept, or ought to accept, his judgment with more respect than that of the most original mind and most brilliant discoverer who has not gone over the historical evidence. Sir John Herschel speaks of Wells's essay "as one of the most beautiful specimens of inductive experimental inquiry," and earnestly recommends it to the student "as a model with which he will do well to become familiar." Dr. Whewell simply characterises Wells's essay as "one of those books which most drew attention to the true doctrine." (See "History of the Inductive Sciences," 3rd ed., 1857, vol. ii. p. 424; see also p. 415.)

Even during the lifetime of the author the essay did not pass unchallenged. Dr. Thomas Young, both a writer and a worker, noticed the book in the *Quarterly Review* for 1814, and says, with bitter satire, that while Dr. Wells "affords us complete information, not only respecting the sentiments of Aristotle and Theophrastus as to the nature and causes of dew, but also of the most distinguished philosophers of modern times, some of the works, however, of the persons whom he mentions, and some of the latest, have most unaccountably escaped his attention." Dr. Young protests against "the total novelty of the opinions, &c.," in the essay.

The reader interested in the subject will find in a little shilling volume published in Weale's series, entitled "Experimental Essays," by Mr. Tomlinson, a minute account of what had been done by Wells's predecessors. Mr. Casella has made free use of Mr. Tomlinson's essay, but, as it seems to us, only so far as it refers to the praise and glory of Wells, omitting all detail that might cast a spot on that bright surface. The language of Wells's essay is that of authority. The writer's tone is everywhere that of a man announcing his own discoveries. For example, he says:—"I have frequently seen, during nights that were generally clear, a thermometer lying on the grass plat rise several degrees upon the zenith being occupied only a few minutes by a cloud." Most of the important steps in the theory are thus stated, as if for the first time; and we agree with Mr. Tomlinson that in the essay "we find only a loose and general reference to authorities, and a very scanty acknowledgment of other men's labours." Nevertheless, "most of Wells's results had been published long before the author commenced his labours, and the theory for which he has obtained so much credit was also similarly indicated in brief but unmistakable terms."

While grateful for a reprint of Wells's essay, we fear the praise bestowed on this edition must be similar to that of the lady on the curate, whose copied sermon she praised, and the only merit he claimed was that of having delivered it. "Ah! that is the only part about it I didn't like." We like Wells's essay, but we do not like the way in which it is "delivered." The book is scarcely improved by the additions. Unless the work had been more thoroughly done, a simple reprint of the edition of 1818, with the short autobiography by way of introduction, would have answered every purpose for which this edition is issued.

In a work that professes to bring the subject down to the present time, it is remarkable that some celebrated researches are unnoticed. Such are Melloni's "On the Nocturnal Cooling of Bodies." The experiments were

conducted in the autumn of 1846, in the valley of La Lava, between Naples and Salerno, and the memoirs, which are beautifully written and of great interest, were read before the Royal Academy of Naples in February and March, 1847. But the most curious point connected with this inquiry is its origin. It will hardly be believed that the Austrian and Bourbon Governments, in their dread of novelty, would not allow the true theory of dew to be taught. Melloni, in order to show that the laws of terrestrial radiation are the same in Italy as in countries where there is more political liberty, undertook these researches. The care with which he prepared his thermometers for observation is worthy the attention of meteorologists.

CONTEMPORARY SCIENTIFIC PRESS.

Under this heading it is intended to give the titles of all the chemical papers which are published in the principal scientific periodicals of the Continent. Articles which are merely reprints or abstracts of papers already noticed will be omitted. Abstracts of the more important papers here announced will appear in future numbers of the Chemical News.]

Journal des Fabricants de Papier. December 15, 1866.

E. Bourdilliat "*On the Chemical Products used in Paper-making.*"

January 1, 1867.—E. NOTICES OF PATENTS.

Communicated by Mr. Vaughan, F.C.S., Patent Agent, 54, Chancery Lane, W. C.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

458. J. H. Johnson, Lincoln's Inn Fields, Middlesex, "Improvements in the application of certain hydrocarbons to the obtainment of light and heat, and in the apparatus or means employed therein." A communication from A. Muller and J. Matheï, Paris.—Petition recorded February 20, 1867.

563. A. A. Croll, Coleman Street, London, "Improvements in the treatment of liquid hydrocarbons for the purpose of obtaining a permanent gas."—February 28, 1867.

579. W. Parry and J. Frearson, Birmingham, "Improvements in treating or purifying sewage, and in apparatus to be used for that purpose."—March 1, 1867.

605. S. Newington, Ticehurst, Sussex, "An improved compound for destroying insects and preventing and checking blight in plants."—March 4, 1867.

611. A. S. Macrae, Liverpool, "Improvements in hydrocarbon oils used for safety and other lamps."

616. J. E. Duyck, Glasgow, N.B., "Improvements in the utilisation of mineral and other oils for the production of heat, and in the apparatus employed therefor."—March 5, 1867.

624. J. Thompson, Nettlebed, Oxfordshire, "Improvements in the manufacture of gas."—March 6, 1867.

647. E. Lloyd, Bow, Middlesex, "Improvements in the treatment or preparation of straw and other fibrous materials for the manufacture of paper."

650. W. Young, Straiton, Midlothian, and P. Brash, Leith, Midlothian, "Improvements in the distillation of bituminous substances."

652. S. C. Salisbury, New York, U.S.A., "Improvements in the manner of reducing aud refining metallic ores, more particularly ores of iron, and in converting iron into steel, and in apparatus to be used in connexion therewith."—March 7, 1867.

657. J. Turner, Queen Street, Stepney, Middlesex, "An improved composition for coating or covering the surface of iron, wood, stone, brickwork, and other substances or materials to prevent oxidation and decomposition thereof."—March 8, 1867.

Notices to Proceed.

2886. W. Darlow, Tottenham, Middlesex, and P. W. Seymour, Canning Town, Essex, "A new magnetic compound applicable to the manufacture of articles suitable for curative and other beneficial and useful purposes."—Petition recorded November 7, 1866.

2947. G. Crawshay, Gateshead-on-Tyne, Durham, and J. Thomas, Newcastle-on-Tyne, "Improvements in the treatment of scoria or slag of copper ores, or scoria from other ores containing iron, in order to extract the iron therefrom, and in refining pig or cast iron to improve the quality of wrought or cast iron."

2948. G. Crawshay, Gateshead-on-Tyne, Durham, and J. Thomas, Newcastle-on-Tyne, "Improvements in refining pig or cast iron for puddling into wrought or malleable iron."—November 10, 1866.

2957. G. Crawshay, Gateshead-on-Tyne, Durham, and J. Thomas, Newcastle-on-Tyne, "Improvements in the treatment of titaniferous iron ores, and in extracting iron therefrom; also for utilising the scoria produced."—November 12, 1866.

3002. W. Grüne, Berlin, "A chemical decoration on gold, silver, and other metals, and colours on porcelain, glass wares, crystal wares, Delft wares, potters' wares, and similar matters, called 'Grüne's process.'"—November 15, 1866.

3030. A. P. Price, Lincoln's Inn Fields, Middlesex, "Improvements in the manufacture of carbonate of soda." A communication from Dr. A. Blügel, Utrecht, Holland.—November 19, 1866.

3066. P. R. M. Le Guen, Rue Voltaire, Brest, Finistère, France, "An improved process for combining tungsten with cast iron, by conglomerating reduced wolfram."—November 22, 1866.

3133. W. R. Lake, Southampton Buildings, Chancery Lane, "Improvements in the manufacture of white lead."

A communication from W. Bell, T. M. Fell, and A. G. Fell, New York, U.S.A.—November 28, 1866.

3112. N. S. Shaler, Cambridge, Mass., U.S.A., "Improvements in preserving animal and vegetable substances."—November 26, 1866.

3152. W. Clark, Chancery Lane, "Improvements in the manufacture of green colouring matter." A communication from J. A. Schlumberger, Boulevart St. Martin, Paris.—November 30, 1866.

3212. P. E. Wissocq, Rue Richepanse, Paris, and Count L. Krasinski, Rue de Penthièvre, Paris, "Improvements in the treatment of ores of metals of which the sulphates are soluble in water."—December 6, 1866.

425. J. Lamble, Southampton, Hants, "A new or improved composition for the coating and preservation of ships' bottoms."—February 15, 1867.

471. H. Wadkin and C. Shepherd, Chester, "Improvements in burning or calcining limestone and cement, and in ovens or apparatus employed for that purpose."—February 21, 1867.

560. S. B. Allen and J. H. Winsor, Massachusetts, U.S.A., "Generating heat by the admixture and combustion of a hydrocarbon vapour, air, and the gaseous components of steam." A communication from H. R. Foote, Boston, Suffolk, Mass., U.S.A.—February 28, 1867.

651. W. H. Towers, New York, U.S.A., "A new and useful process whereby leather, wholly or partially tanned, or animal tissue of any nature, is made hard, semi-elastic, and transparent, and rendered a fit material from which to manufacture combs, buttons, buckles, eye-glass frames, splints, knife-handles, articles of jewellery, and other articles now produced from vulcanised india-rubber."—March 7, 1867.

CORRESPONDENCE.

Decolorising Green Bottle-Glass.

To the Editor of the Chemical News.

Sir,—In reference to your Siberian correspondent's inquiry on the above subject in your last issue, I beg to say that I have used, on a large manufacturing scale, with much success, arseniate of soda, or a mixture of white arsenic, soda ash, and nitrate of soda, for decolorising silicate of soda made from sulphate of soda, silica, and coal.

I am, &c. B.A., B.Sc.

April 3.

Eudiometric Analysis of Ammonia.

To the Editor of the Chemical News.

Sir,—Not a few, doubtless, of the readers of your valuable periodical are chemical lecturers interested in the effective experimental demonstration of the volume composition of Gerhardt's types. This seems evidenced by your publication of Dr. Hofmann's lecture illustrations in vol. xii., and by the large sale of that Professor's "Introduction to Modern Chemistry," in which the same are detailed.

Suffer me, then, to mention, as a modification of these experiments, that the volume composition of ammonia may be readily shown by explosion with oxygen in the eudiometer, thus enabling the teacher to assimilate the mode of investigation of this type to that of H_2O and HCl, and to dispense with a tedious quantitative operation—viz., the decomposition of liquor ammoniæ by a measured bulk of chlorine.

The few precautions are sufficiently obvious—viz., first, to use a considerable excess of oxygen to mitigate the otherwise violent detonation; secondly, to previously dry the eudiometer and gases, both to avoid absorption of the NH_3 and to remove, as far as possible, the additional expansive force of the steam generated at the moment of ignition.

The following are the numbers of a rough experiment at the lecture table, which followed, in order, Hofmann's illustration, Fig. 11, p. 56, vol. xii. Chemical News, proving the condensation of the ammonia molecule to be ½, and which replaced that previously explained by him, Figs. 8 9, 10, on the preceding page:—

Analysis of Ammonia.

Volume of	dry ammonia	86	c.c.
,,	ditto, supposed resolved into its elements	172	,,
,,	oxygen added	126	,,
,,	sum of H, of N, and of O	298	,,
,,	after explosion	105	,,
,,	diminution	193	,,
,,	hydrogen = ⅔ of loss	128·6	,,
,,	nitrogen (by subtraction)	43·4	,,

A result closely conformable with the prediction of the formula NH_3.

It appears, consequently, that, by using these proportions of the gases, the production of oxides of nitrogen is inconsiderable.

I am, &c.

B. W. Gibsone, F.C.S.

City of London College, March 25.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Reduction of Organic Compounds.—M. Berthelot. Researches commenced by Berthelot, in 1855, on the use of iodhydric acid as a reducing agent, and continued until now, and results obtained by other investigators, have furnished sufficient materials for constructing a general method of reduction, which is fully developed in this paper, to which the reader must be referred for details. The author considers that the facts described furnish a general method for the reproduction of the fundamental hydrocarbon from any of the bodies composing the carbon series, of which it is the basis. In this respect incomplete compounds behave like complete ones, the first action of the iodhydric acid being to convert the former into the latter. The remarkable facility with which iodhydric acid parts with its hydrogen under the conditions of the experiments described, appears to result from the operation of thermochemical laws. The quantity of heat disengaged on the formation of one equivalent of iodhydric acid from iodine and hydrogen may be estimated at 1400 units, whilst the formation of bromhydric acid sets free 13,200 units, and that of chlorhydric acid 23,800 units. A glance at these figures enables us to understand why iodhydric is very much less stable than either bromhydric or chlorhydric acid, and that the slightest change in the state of the body in presence of iodhydric acid may establish a reaction by furnishing the small amount of energy necessary for the decomposition of the acid. Moreover, at 275°, the temperature at which the normal reactions occur, iodhydric acid is in so unstable a condition of equilibrium, that it begins to decompose spontaneously.—(*Bull. Soc. Chim. Paris*, 1867, 53.)

Nitriles.—L. Henry. Acetonitrile combines, with disengagement of heat, with dry bromhydric and iodhydric acids. The resulting compounds are crystalline white solids, deliquescent, soluble in alcohol, insoluble in ether, decomposing rapidly in moist air, with formation of acetic acid and ammonic salts. Caustic alkalis effect the analogous change; the corresponding compound with chlorhydric acid it is difficult, that with cyanhydric acid apparently impossible, to obtain. Acetonitrile also combines with silicic chloride.

Benzonitrile, which is best prepared by phosphoric pentachloride and benzamide, behaves, under similar conditions, like acetonitrile.

Ethylic and allylic sulphocyanides combine with dry bromhydric and iodhydric acids, but allylic sulphocyanide appears not to combine with chlorhydric acid.

Acetylic bromide forms a crystalline compound with acetonitrile and with allylic sulphocyanide.—(*Bull. Soc. Chim. Paris*, 1867, 85.)

Naphthalene (C=6).—E. J. Maumené. The theory of chemical action propounded by the author has conducted him to the discovery of several new hydrocarbons. Naphthalene heated with argentic oxide to 250°, or with cupric oxide to 400°, or even to a dark red, gives, even though a great excess of oxide be employed, various bodies all magnificently crystalline, among which are *nonolène* $C_{18}H_8$ ($\frac{1}{2}$ chrysene), *octojiène* $C_{16}H_6$ (dracene), *hexahène* $C_{12}H_4$. Full details are promised.—(*Bull. Soc. Chim. Paris*, 1867, 72.)

Nomenclature of Hydrocarbons (C=6).—E. J. Maumené. It is proposed that the names of all hydrocarbons terminate in -ene; also—(1) considering C_2H_2 as a molecular unit, that in the series $C_{2n}H_{2n}$ the value of n be expressed by the words mono-, di-, &c.; (2) that in the series $C_{2n}H_{2n-x}$, in which carbon predominates, the letter of the alphabet corresponding by its numerical order to the value of x be interposed between the words mono-, di-, &c., and the general termination -ene; (3) that in the series $C_{2n}H_{2n+x}$, in which hydrogen predominates, the particle hydro-, coupled with the letter expressing, as in (2), the value of x, be interposed between the words mono-, di-, &c., and the general termination -ene. To give an idea of the names so constructed, the following are selected from the fourteen groups given in detail by the author:—$C_{2n}H_{2n+2}$ marsh gas, C_2H_4 monohydrobene; $C_{2n}H_{2n+1}$ ethyl, C_4H_5 dihydrene; $C_{2n}H_{2n}$ ethylene, C_4H_4 diene; $C_{2n}H_{2n-1}$ allyl, C_8H_5 triaene. Polymers are expressed by using indices: thus, for polymers of phenyl, $C_{12}H_5$ hexagene, $(C_{12}H_5)^2$ hexagene^2, $(C_{12}H_5)^3$ hexagene^3. Compounds of two hydrocarbons, as allyl-phenyl, become triaene-hexagene. A table of the general composition of hydrocarbons, giving the proportions between (1) the number of equivalents, (2) the equivalent weights, (3) the simple weights, for each hydrocarbon, and which the author believes to be pregnant with interest, concludes the paper.—(*Bull. Soc. Chim. Paris*, 1867, 73.)

Aromatic Compounds, Reduction of (C=12, O=16).—A. Baeyer. Phenol vapour is reduced by hot zinc powder to benzol and some other bodies, among which is, perhaps, phenyl-ether. Benzoic and phtalic acids give bitter almond oil. Oxindol C_8H_7NO (*Zeitschr. Chem.*, N.F., ii. 685) gives indol C_8H_7N, resembling naphthylamine in properties, distilling at a high temperature, condensing to an oil, and presently crystallising. A pine-wood splinter moistened with chlorhydric acid and indol becomes cherry-red.—(*Zeitschr. Chem.*, N.F., iii. 90.)

Saline Solutions, Relative Volumes of.—J. Regnauld. The tabulated results accompanying this paper show that aqueous solutions of ammonia and of potash and soda behave differently when mixed with acids; the first shows a contraction, the second and third an expansion, yet in each case much heat is evolved. The change of volume is of the same sign, whatever be the nature of the acid used. The amount of change of volume for the same base depends on the acid saturating it. Potash and soda differ very little in these respects. Ethylamine and nicotine behave like ammonia—that is to say, they contract in uniting with acids. Lithia, baryta, lime, thallia, and tetrethylammonic hydrate belong to the potash and soda series—that is to say, they expand in uniting with acids.

The explanation of these phenomena is this: Ammonia dissolves in water, but does not combine with it to form a compound of any appreciable degree of stability. Contraction normally accompanies the production of ammonic salts. Potash and soda form very stable hydrates, which, in presence of acids, interchange with them. The elements of the salt formed contract in combining, and the water set free from the hydrates expands in escaping. The difference between the results of these two phenomena distinguishes the ammonia from the potash type.—(*Journ. Pharm. Chim.* [4] v. 81.)

Gum, Bleaching of.—Picciotto. Dissolve gum in 6—15 parts of water, filter through a cloth; with the filtrate mix recently precipitated alumina, and filter again. The alumina may be used twice; it may also be revived by washing with hot water, treating with chloride of lime or chlorine water, and washing with boiling water.—(*Polyt. Notizbl.*, 1865, 282.)

Cetene, Derivatives of (C = 12, O = 16).—J. J. Chydenius. Cetene, $C_{16}H_{32}$, prepared from cetylic alcohol and phosphoric anhyride, combines eagerly with bromine, forming $C_{16}H_{32}Br_2$, a yellowish liquid heavier than water, which decomposes if distilled, even though *in vacuo*, and, if treated with alcoholic solution of potash, gives $C_{16}H_{31}Br$, a yellow liquid lighter than water. Cetene combines with chlorine, but the results are not described, being difficult of preparation. Monobromcetene distilled with lime or sodic ethylate gives cetylene, $C_{16}H_{30}$, the highest known homologue of acetylene, colourless, oily, lighter than water, distilling undecomposed, melting at −25°, boiling at 280—285°, easily soluble in alcohol and ether, combining with Br_2 to form a yellow liquid heavier than water, very easily attacked by alcoholic solution of potash with reproduction of cetene. An attempt to prepare the diatomic alcohol failed.—(*Comptes R.* lxiv. 180.)

Pseudomorphine (C=6, O=8).—O. Hesse. From the small quantity he obtained, Pelletier, who discovered pseudomorphine thirty years ago, was unable to give precise directions for its preparation, and naturally enough doubt fell on its identity. Hesse finds that it accompanies morphine in Gregory's method, and may be separated from that body by adding excess of ammonia to the alcoholic solution of both alkaloids; the morphine is precipitated, the other remains in solution. Pseudomorphine is tasteless, insoluble in water, alcohol, ether, chloroform, carbonic bisulphide, and dilute sulphuric acid, easily soluble in potash, soda, or lime solutions, and in alcoholic solution of ammonia, sparingly so in aqueous solution of ammonia; it does not neutralise the acid reaction of even the smallest quantity of chlorhydric acid; it dissolves in concentrated sulphuric acid with an olive green, in concentrated nitric acid with an intense orange red, in ferric chloride with a blue colour. At 120° it loses 2 eq. water of crystallisation; at higher temperatures it turns yellow and decomposes without melting. Its formula is $C_{34}H_{19}NO_8$, containing therefore O_2 more than morphine, but it does not result from an oxidation undergone by morphine in its preparation; it may, however, be identical with Schützenberger's oxymorphine obtained by acting on morphine with potassic nitrite. Platino- and auro-pseudomorphinic chlorides are amorphous; the sulphate is very like calcic sulphate. The oxalate, tartrate, nitrate, chromate, chloride, and iodide are described: they are sparingly soluble; the crystalline precipitate with mercuric chloride is very little soluble in chlorhydric acid.—(*Ann. Chem. Pharm.* cxli. 87.)

Nitrogen and Carbon in Iron and Steel.—L. Rinman. To determine nitrogen the sample is dissolved in chlorhydric acid (sp. gr. 1·12), air being excluded; the ammonia formed is expelled by lime and titrated. Numbers so obtained did not reveal any connexion between the quality of the steel and its percentage of nitrogen. The iodine method for determining the total carbon is sufficiently accurate. Tempered steel dissolves in hot or cold chlorhydric or sulphuric acids without carbonaceous residue; untempered steel dissolves in hot acid without, in cold acid with, carbonaceous residue. Iron dissolved in acid sets free carbon in three states: as graphite in pig iron, as ferrocarbon in untempered steel, as hydrocarbon in tempered steel. Numbers obtained from different samples of iron are given.—(*Oefvers. af Akad. Förh.* xx. 443.)

MISCELLANEOUS.

The Royal Society.—The candidates for the title F.R.S. this year are more numerous than we have ever before known them to be. They are sixty-one in number, and comprise several gentlemen whose names are well known to the readers of the Chemical News. Amongst them we notice B. F. Duppa, Esq., author of numerous chemical researches, published in the *Philosophical Transactions*, conjointly with Dr. Frankland; P. Le Neve Foster, Esq., Secretary of the Society of Arts; Daniel Hanbury, Esq., Pharmaceutical Chemist; A. G. Vernon Harcourt, Esq., Secretary of the Chemical Society; Jabez Hogg, Esq., the well-known microscopist; E. J. Lowe, Esq., the meteorologist; Nevil Storey Maskelyne, Esq., Keeper of the Mineral Department, British Museum; George Matthey, Esq., the eminent metallurgic chemist; B. W. Richardson, M.D., of local anæsthesia celebrity; Charles Tomlinson, Esq., natural philosopher; Cromwell Varley, Esq., the electrician; J. A. Wanklyn, Esq., Professor of Chemistry at the London Institution; H. Wilde, Esq., whose electro-magnetic machine has attracted so much attention lately; and James Young, Esq., the discoverer of the process for making paraffin and paraffin oils in large quantities from coal. It will be noticed that among this list there are no less than five well-known chemists. It is very improbable that all these will be chosen, as the rule of late years has been to elect not more than two, and occasionally three, chemists.

Gun-cotton.—An important communication was made to the Royal Society on the 4th instant by Professor Abel, F.R.S. The subject was a continuation of the researches which this chemist has been carrying on for some years past, and treated principally of the causes which interfere with the keeping properties of gun-cotton. Gun-cotton prepared in the most careful manner has had the reputation of being somewhat uncertain in its keeping properties, and the object of these researches has been to ascertain the special conditions which would determine or prevent this decomposition. Several important points were mentioned in this paper. Thus, exposure to light was found to be a powerful cause of decomposition, and this was especially the case when the gun-cotton was very dry; moisture prevented this, and when the gun-cotton was palpably damp it could be preserved unchanged for a very long time. The speaker said that he had kept it in this manner for three years without the slightest deterioration being perceptible; he had no reason to suppose that it would not keep in this state for any length of time. Acids likewise exerted a very prejudicial influence on the stability of gun-cotton; alkalies, on the contrary, preserved it. This was stated to be the probable explanation of the superior keeping qualities of Baron von Lenk's gun-cotton, which received a final soaking in an alkaline silicate, the slight alkalinity thus conferred upon it having a very beneficial effect. Soaking in dilute solution of carbonate of soda was stated to exert an equally good action. Gun-cotton might be preserved in any quantity with absolute safety if it were kept damp. As an illustration of this fact, Professor Abel took a large ball of damp gun-cotton in his hand, and deliberately plunged a red-hot poker into the middle of it. Steam and smoke were evolved in abundance, but no further decomposition was effected beyond that produced by the actual contact with the hot iron. The lecture was very long, and contained many other interesting facts. We shall probably lay an abstract of it before our readers in an early number.

Whilst speaking of gun-cotton, many of our readers will feel interested in knowing that Messrs. Prentice and Co. are now manufacturing compressed gun-cotton, according to Professor Abel's process, for mining and quarrying purposes. The principle thus introduced secures the utmost safety and stability, whilst it increases its explosive force for equal bulks to six times that of gunpowder. If the blast is effected with no more gun-cotton than is really necessary, the air is left comparatively free from deleterious gases. The great advantage which gun-cotton possesses over gunpowder in this respect is of the highest importance when the health of the miner is considered. Dr. Angus Smith, F.R.S., in his report to Parliament upon the "Sanitary Effects of Gun-cotton," says:—"If gun-cotton could be used of a kind which gives out none of the oxides of nitrogen, an advantage of the most pleasing kind would be gained. The solid matter, the crystals and carbon, would cease to trouble the miner, as well as the sulphur compounds that follow every explosion. In every trial in which the effect on the senses or the breathing, and as far as we can judge on health, was considered, gun-cotton has come off with the highest character. I feel much confidence in speaking thus highly in its favour."

Chemical Toys.—Dr. Divers, Lecturer on Natural Philosophy at Charing-cross Hospital, corroborates, in the following letter to the *Times*, what we have so often insisted on in these pages. He says:—"Is it not time the public were cautioned against the dangers of 'chemical toys?' more especially as the printed assertions often sold with them, making them out to be harmless, are not to be relied upon. Within the last two years or so a great number of these toys have been brought out, most of them either highly poisonous or dangerously combustible. Thus, 'Pharaoh's Serpents,' composed of sulphocyanide of mercury, are highly poisonous, and during combustion evolve most noxious vapours. 'Larmes du Diable,' formed of metallic sodium, burn with great violence if they are either heated or moistened with water—in this respect exceeding phosphorus in danger—and scatter caustic alkali about the place when they are used as directed. 'Sunshine in Winter Evenings' and 'Fiery Swords,' formed of magnesium, are apt in the hands of children to cause nasty burns, through the rapidity of their combustion and the molten and white-hot particles they cast off. 'Sensation Cigarettes,' charged with guncotton, project, when fired, very noxious vapours into the mouth; 'Will o' the Wisp Paper,' 'Parlour Lightning,' 'Fireflies,' 'Aërial Glow-worms,' &c., all formed of pyroxylin, or paper rendered explosive by the action of concentrated nitric and sulphuric acids, are highly inflammable and dangerous—the latest proof of which is the terrible accident last week at Mr. Laidlaw's workshop. I have myself known bad injuries caused by experimenting with sodium and water, and also with flowers of sulphur and chlorate of potassium, the rubbing together of which in small quantities is so often recommended in books on 'Parlour Magic,' &c., as an amusing experiment, quite free from danger. The use of chemical toys in educating children in the science of natural phenomena must be exceedingly slight, and quite incommensurate with their danger."

London Water.—After a lapse of some months we return to this subject—one of vital importance—treated then, as our readers will remember, in full detail. We can now report the progress that has been made since that time, and Professor Frankland, by his high authority, enables us to show how fully our conclusions have been justified. From the very first we showed the great importance of a separate estimate of the nitrogen of the organic matter; this we pointed out in December, 1866, and, with less fulness, even before that. The *Lancet* and other medical journals quoted this suggestion as being promising, and we therefore feel the greater satisfaction in Dr. Frankland's demonstration of that fact. The future returns of the Registrar-General will, we expect, contain the total amount of nitrogen in the water, the nitrogen of the ammonia, of the nitrates and nitrites respectively, and lastly the deduced nitrogen of the organic matter in water. Dr. Frankland shows, also, clearly that the total nitrogen of the water has a kind of geological value, being the skeleton, as he fitly terms it, of the pre-existing nitro-

genised organic matter from sewage pollution. Thus, in future reports the nitrogen will hold a place of honour, in giving unmistakable evidence, both as regards past and present pollution, during every month of the year. This tabulation of results separately has been made by Dr. Frankland as yet only for one month—March, 1867—but it teaches the important fact that there was not a trace of organic nitrogen in any metropolitan water during the month. We may conclude, therefore, as Dr. Letheby has often remarked in his returns for the City of London, that London water is now harmless as far as the organic matter is concerned, and that it is to all intents and purposes a good potable, if not a very soft, water. Mention was also made by Dr. Frankland of the ill-effects resulting from the Old Ford reservoir water—effects so accurately traced by him; and this also bears out our opinion, that engineering defects, local or general, have, in almost every recent case, accounted for outbreaks of epidemic disease, whether local or general. The most important want at present also requires a remedy at the hands of the engineer, and that is a constant pressure supply. Without this there cannot fail to be occasional repetitions of the tale of the Old Ford reservoir. Dr. Frankland here again spoke of this as a matter of the highest importance. After all, then, the chemical bearings of the water question are not so momentous as others as far as the spread of disease is concerned; but as regards the utilisation of sources of supply given by nature close at hand, they yield to no others. We think, as we thought before, that the political considerations connected with a source of supply 200 or 300 miles from the place of consumption, cannot be too often brought under discussion. The magnitude of the interests at stake, and a degree of settlement for some time that should also be effected, could not fail to invest the subject with the interest that it has now, but had not a short time ago, acquired. We learn, therefore, with great pleasure that the commission appointed at the beginning of the year to report upon two of the schemes before the public, will take into consideration also other proposed sources of supply.

Composition and Quality of the Metropolitan Waters in March, 1867.—The following are the Returns of the Metropolitan Association of Medical Officers of Health:—

Names of Water Companies.	Total solid matter per gallon.	Loss by ignition.*	Oxidisable organic matter.†	Hardness.	
				Before boiling.	After boiling

* The loss by ignition represents a variety of volatile matters, as well as organic matter, as ammoniacal salts, moisture, and the volatile constituents of nitrates and nitrites.

† The oxidisable organic matter is determined by a standard solution of permanganate of potash, the available oxygen of which is to the organic matter as 1 is to 8; and the results are controlled by the examination of the colour of the water when seen through a glass tube two feet in length and two inches in diameter.

Hy. Letheby, M.B.

Precautions against Cattle Plague on the Continent.—The *Moniteur Belge* states that, by order of the Custom-house authorities of the kingdom of Prussia, the importation into Prussia from Holland, Belgium, and the Grand Duchy of Luxemburg, of the following articles is rigorously prohibited, in order to guard against the chance of bringing into Prussia the cattle disease,—viz., all horned cattle, sheep, pigs, goats, dogs, cats, pigeons, or any other kind of fowls, *dead* or *alive*, tallow, suet, lard, fresh, salted, or cured meat, dry or raw or salted hides, all kinds of hair, horns, and feathers, bones, animal offal, old clothes, rags, all forage or fodder for cattle, hay, straw, raw wool, dung material, except Peruvian guano which is certified to have come by sea; it is further strictly forbidden to import into Prussia any materials (earthenware, glass, &c.) packed in hay or straw. To convey to our readers some idea of the severity of this measure, it must be understood that it affects an unbroken line of land frontier of no less an extent than a length from north to south stretching over 364 English miles, reaching from the northern corner of the province of Groningen to the place where the Grand Duchy of Luxemburg meets French territory southward. To the westward of this line lives and thrives an aggregate population numbering fully ten millions of people.

ANSWERS TO CORRESPONDENTS.

*** In publishing letters from our Correspondents we do not thereby adopt the views of the writers. Our intention to give both sides of a question will frequently oblige us to publish opinions with which we do not agree.

Vol. XIV. of the Chemical News, containing a copious Index, is now ready, price 11s. 0d., by post, 11s. 6d., handsomely bound in cloth, gold-lettered. The cases for binding may be obtained at our Office, price 1s. 6d. Subscribers may have their copies bound for 2s. 6d. if sent to our Office, or, if accompanied by a cloth case, for 1s. Vols. I., II., and VII. are out of print. All the others are kept in stock. Vol. XV. commenced January 4, and will be complete in 26 numbers.

Articles by Dr. Odling, Professor J. Stas, Mr. Crookes, M. Stahlschmidt, J. Wallace Young, C. A. Seely, and R. C. C. L. are in type, but are unavoidably postponed through press of matter.

M. M. Y.—Plumbago is a very good lubricator. A better one may be made by mixing it with tallow and wax.

J. Simpkin.—The book can be sent from our office by remitting its price in stamps to the publisher.

H. N. Draper is thanked for his communication. The information shall be forwarded.

J. Thomas.—Received, with thanks.

Graphitoidal Boron.—The information referred to is contained in an original article communicated by Professor Wöhler to the Chemical News more than a month ago.

A. B. is informed that, at several places in this country and elsewhere, illuminating gas (or vapour) is successfully produced, on a considerable scale, by conducting a current of air through the generators and volatile hydrocarbons of the Photogenic Gas Company, Stratford, Essex, to which Company he can apply for any further desired information on the subject.

A Constant Subscriber.—It is beyond our province to answer such questions as you put. The information sought is more engineering than chemical, and can only be obtained by applying where the processes are in full work. Dilute sulphuric acid will certainly injure cast-iron boilers; the vessels for this purpose should be of lead or Yorkshire flags.

Constant Reader.—The statements will certainly not pass muster amongst scientific chemists; but as it cannot be imagined that the author was ignorant on this point, it must be supposed that he preferred the simpler explanation as being within the capacity of a non-scientific audience.

Retention of Nitric Oxide.—H. B. Gibbins writes:—"An iron pipe at one time used for conveying sulphurous acid fumes into a chamber had been out of use for certainly eight years, and was choked up. On its being broken up for old iron, the solid mass contained in it gave off red fumes of nitric peroxide; so I conclude that either that or nitric oxide must have been imprisoned in a solid form all these years whilst the pipe had been disconnected from the chamber."

W. H. Harrison.—1. We know nothing better than good copal varnish for coating photographic transparencies on opal glass. Probably some compound of silica, such as its aqueous solution, one of its ethers, or an alkaline salt, might be made to answer, but experiments on this subject are wanting. 2. In experiments with the spectrum camera, the writer found that no alteration in the alkaline and metallic bases united with the chlorine, bromine, or iodine in the collodions used had the slightest influence on the length of the spectrum photographed. 3. The spectrum camera described by the writer in vol. ii., page 292, of the *Journal* of the Photographic Society, gave a spectrum about three inches long. In order to increase the length of the spectrum without altering the size of the apparatus, the lens which projects the image of the spectrum on to the screen (which was twelve inches focal length) must be shortened in focus or placed nearer the slit. 4. The nomenclature complained of is being generally adopted in chemical literature. It has many advantages over that formerly in use.

Received.—B. W. Gibsone, M.A., &c.; C. H. (a subscriber).

Books Received.—"Proceedings of the American Pharmaceutical Association at the Fourteenth Annual Meeting held in Detroit, Mich., August, 1866."

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On the Correct Adjustment of Chemical Weights, by William Crookes, *F.R.S.*

A set of grain or gramme weights, as ordinarily supplied by even the best instrument-maker, is never absolutely exact. However carefully they may be adjusted, the pieces of metal which respectively represent 1000 grains, 100 grains, 10 grains, &c., are only more or less approximations to the true weights. It is impossible for any one to adjust them with absolute accuracy. Indeed, the best makers readily acknowledge this, and are careful not to guarantee the correctness of their weights beyond certain limits.

In most chemical analyses the error arising from inaccuracies in the weights used is so small in comparison to errors of manipulation, or to imperfections inherent in the chemical processes adopted, that it may generally be disregarded; but when the chemist has for his object the determination of an atomic weight, or is engaged in other researches demanding the highest refinement of accuracy which chemistry and physics can supply, then he is bound to neglect no correction which will increase the precision of the results.

That chemists, whose well-trained reasoning powers allow them to take for granted nothing which is capable of experimental verification, and who insist upon the utmost attainable precision in their balances, should, as a rule, entirely neglect the probable errors which the inaccuracies of their weights may introduce, is somewhat surprising.

For the four last years I have been engaged in an investigation, the results of which will shortly appear in this journal. In carrying out this investigation, it has been my endeavour to avail myself of every possible refinement to insure accuracy. In order to eliminate the errors introduced by varying atmospheric pressure, the weighings, and many of the chemical reactions have been performed in a vacuum. It is not my intention in the present paper to discuss the subject of weighing *in vacuo*; but as many friends from time to time, whilst witnessing my methods of weighing, have expressed a wish to have placed on record, for future reference, the plan adopted for adjusting weights, and as, moreover, I am not cognisant of the existence of any published directions, except those cited below, I am induced to place a short notice of my method of procedure before the readers of the Chemical News. Let me commence by disclaiming any originality in the process. Professor W. H. Miller, of Cambridge, in his classical researches on the determination of the standard pound (*Philosophical Transactions* for 1856, pp. 811, 827, 937), has given full directions for attaining a similar object. These, however, will not exactly apply to the systems of weights used by chemists; for of the three cases described by him, the former two concern a peculiar system of weights, and in the third, two sets of weights, one for the Exchequer, the other for the Royal Mint, were compared at the same time. To this paper, as well as to the learned author himself, I am indebted for an immense store of valuable information on the subject of weights and weighings.

It may make this description clearer if I give exactly as they were performed the details of the adjustment of a set of brass grain-weights, with which some of my earlier researches were carried out. These weights, new, and made by one of the best English firms, Messrs. Ladd and Oertling, may, therefore, be considered as accurate a set as any in ordinary use.

For nearly every process in which weights are used in chemistry, the object is not to ascertain the *absolute* weight of a substance in terms of a grain or gramme, but to determine its *relative* weight, in comparison with that which it possessed at some other time before it was submitted to certain analytical or synthetical operations. If the weighings are performed with the same weights, it does not at all matter whether the weights are absolutely of the value which they profess to be, but it is very important that they should bear a known proportion to each other. The highest weight (1000 grains) in the set should be taken as the standard. It is immaterial whether or not this is accurately 1000 standard grains,* but, *calling it* 1000 grains, the value of the other weights should be known in terms of this weight with the greatest attainable accuracy.

The first operation consists in taking the specific gravities of each brass weight. The density of the larger weights must be ascertained at least to the second place of decimals, and that of the smaller ones to the first place. The specific gravity of each weight should be separately determined; for brass weights, even of the same set, differ greatly in density among themselves. A variation of not more than 0·5 in the specific gravity of the 1000 grain weight, will cause a difference in the amount of air it displaces of about 0·001 grain.

The balance being brought into equilibrium, the 1000 grain weight is placed in the left pan, and in the right are placed the 600, the 300, and the 100 grain weights. It is now found that, to bring the balance back to equilibrium, a slight additional weight has to be placed on the right side, to supplement the three weights already in that pan. This is noted. The weights are then removed to the opposite pans, the 1000 grains being on the right, and the three smaller weights on the left. It is now found that a small weight has to be subtracted from the side carrying the three weights, in order to produce equilibrium. The weights are removed and interchanged in this manner ten times, so as to eliminate, as far as possible, the errors arising from observation, or the unequal expansion by heat of the arms of the balance; and by applying the method of least squares to the results obtained, we at last arrive at the equation

$(1000)\dagger = (600) + (300) + (100) + 0{\cdot}00106$ grains . . . *a*

In a similar manner the values of the (600), the (300), and the (100) weights are ascertained in terms of the other weights, thus—

$(600) = (300) + (200) + (100) - 0{\cdot}00485$ grains . . . *b*

$(300) = (200) + (100) - 0{\cdot}00574$ grains . . . . *c*

$(200) = (100) + (60) + (30) + (10) + 0{\cdot}00057$ grains . *d*

$(100) = (60) + (30) + (10) + 0{\cdot}00105$ grains. . . . *e*

We now have data for ascertaining the absolute values of the larger weights in terms of the (1000) weight, taken as standard. Adding *a* and *b* together gives—

$(1000) = 2(300) + (200) + 2(100) + 0{\cdot}00591$ grains . . *f*

Multiplying *c* by 2 gives—

$2(300) = 2(200) + 2(100) - 0{\cdot}01148$ grains . . . *g*

Subtracting *e* from *d* gives—

$(200) = 2(100) - 0{\cdot}00048$ grains . . . . . *h*

* This must be understood as referring only to ordinary chemical research in synthesis or analysis. In many physical investigations it is of great importance that the 1000 grain weight should really represent 1000 normal grains, or that its deviation from that value should be accurately determined. But I confess I do not know where a standard weight suitable for such a comparison is to be me with.

† For distinctness, when speaking of the pieces of brass which are stamped 1000, 600, 100 grains, &c., I represent them by their nominal value enclosed within brackets.

Now, by adding f, g, and three times h, we get—

$$(1000) = 10(100) - 0{\cdot}00701$$

$$\therefore \frac{(1000)}{10} = (100) - 0{\cdot}000701.$$

and

$$\therefore (100) = 100{\cdot}000701 \text{ grains.}$$

Substituting this value for the (100) weight, we get from equation e—

100·000701 grains = (60) + (30) + (10) + 0·00105 grains,

or

(60) + (30) + (10) = 99·999651 grains.

From equation d we get—

(200) = 100·000701 + 99·999651 + 0·00057 grains.

or

(200) = 200·000922 grains.

From equation c we get—

(300) = 200·000922 + 100·000701 − 0·00574 grains,

or

(300) = 299·995882 grains.

From equation b we get—

(600) = 299·995882 + 200·000922 + 100·000701 + + 0·00485 grains,

or

(600) = 600·002355 grains.

The next step is to ascertain the value of the smaller weights. It is now necessary to obtain a second 10 grain weight. This I will call (x); and I will assume that—

$$(60) + (30) + (10) = 100 \text{ grains} \pm i.$$

(In this case, from equation e, the value of i is seen to be − 0·00035 grain.)

By an exactly similar mode of intercomparison, the following equations are now obtained:—

$(60) = (30) + (20) + (10) + 0{\cdot}00270$ . . . . . k

$(30) = (20) + (10) - 0{\cdot}00037$ l

$(20) = (10) + (x) - 0{\cdot}00103$ . . . . . m

$(10) = (x) \pm 0{\cdot}00000$ . . . . . n

Then, by repeating the above process of adding, multiplying, or subtracting, we finally get the true values of these smaller weights. The same process is then to be extended to the whole of the other weights.

The value of the weights thus given is, however, their weight in *air* of the ordinary pressure. It therefore becomes necessary to reduce them to what they would be worth in a vacuum. All bodies displace a bulk of air equal to their own volume, and the weight of this air is therefore greater as their specific gravity diminishes. In delicate investigations this loss of weight in air is important; for 7000 grains of brass displace, roughly, one grain of air.

By proceeding according to known rules, the value of the weights *in vacuo* is finally ascertained, and the results are embodied in the following table.‡ It is assumed that the (1000) weight really weighs 1000 grains in air:

Names of the weights.	Value in air in terms of the (1000) grain weight.	Value *in vacuo* in terms of the (1000) grain weight.	Weight of air displaced by each.	Volume of weights in grs. of water of maximum density.
	grains.	grains.	grains.	
(1000) .	1000·0000	1000·1462	0·1462	119·193
(600) .	600·0023	600·0904	0·0881	71·812
(300) .	299·9959	300·0401	0·0442	36·035
(200) .	200·0009	200·0303	0·0294	23·930
(100) .	100·0007	100·0153	0·0146	11·868
(60) .	60·0007	60·0091	0·0084	7·140
(30) .	29·9988	30·0040	0·0052	3·538
(20) .	19·9991	20·0030	0·0039	2·358
(10) .	10·0001	10·0015	0·0014	1·166

these corrections are individually small, it

‡ ...uding the table to unnecessary limits, I omit the ...ains.

is not right to assume that they may be neglected. The weights submitted to the above adjustment were exceptionally good, and must not be considered as fair representatives of those usually employed in analysis. I have met with weights in which the deviations from their true values were one hundred times as great as in the foregoing instance; and as no one can be certain that some of his weights are not faulty, it is best to ascertain their relative values once for all; for as the deviations are sometimes in excess and sometimes in defect, they are liable to accumulate in one or the other direction, and thus produce errors in weighing of considerable magnitude.

Having ascertained their true value, the weights ought to be carefully preserved. No attempt should be made to get them more accurately adjusted by adding to or removing portions of the metal, and they should not be picked up with metal forceps, as they suffer thus by wear and become lighter.

When possible the chemist should always use platinum weights. After adjusting the weights in question, I found that, owing to the accumulation of tarnish on their surface, there was danger of their becoming faulty. I accordingly procured from Messrs. Johnson and Matthey another set, the separate weights of which were turned out of bars of well-fused platinum. After having bestowed several months' labour upon them, I have now the satisfaction of knowing that they are as near perfection as could reasonably be expected. They have been in use for nearly three years, both in air of the ordinary pressure and *in vacuo*, and comparisons made a few days ago show that their values remain absolutely unaltered.

On Natroborocalcite, its Formula and Associations, by Professor How, *D.C.L., Windsor, Nova Scotia.**

In this journal, February 22, 1867, Dr. G. Lunge proposes a new formula for boronatrocalcite, which interesting mineral, he says, has been examined by many chemists with varying results, some declaring it to be a borate of calcium containing sodium salts as impurities, while more judicious inquirers have found it to be a double borate of calcium and sodium. He quotes Dr. Kraut as proving from former analyses and his own that, by duly allowing for never-failing admixtures, the composition of the mineral is represented by an expression which he calls Kraut's formula. Now, since no date is given for Dr. Kraut's investigation, and, from the references in Dr. Lunge's paper, it appears to be quite recent, I beg to point out that about ten years ago (*Edin. New Phil. Journal*, July, 1857, and *Silliman's Journal*, September, 1857) I proposed the formula attributed to Dr. Kraut as correctly representing the composition of natroborocalcite, found here in an altogether new geological position — namely, in gypsum after it had been carefully washed with cold water till free of sulphuric acid, of which the unwashed mineral contained a little over 1 per cent. with a trace of chlorine. All the soda remaining would of course be as borate, and I found percentages agreeing very closely with those required by the formula I gave—viz.:

	Found.	Calculated.
Soda . . .	7·21	7·82
Lime . . .	14·20	14·12
Boracic acid .	44·10	44·02
Water. . .	34·49	34·04
	100·00	100·00

* Communicated by the author.

from which it is obvious that I had very good grounds for the expression referred to—

$$NaO,2BO_3+2CaO,3BO_3+15HO,$$

which Dr. Lunge calls Kraut's formula, and rejects from finding in his own analysis more water and less soda and lime.

With regard to natroborocalcite having been considered to be a borate of calcium, I may state that I subsequently (*Silliman's Journal* and *Edin. New Phil. Journal*, 1861) collated nine analyses, which were all I could then find as having been made of the mineral, and, as two of them showed no soda, pointed out the probability of there being two species confounded under the same appellations. This has been accepted as the real state of the case (Tenth Supplement to Dana's Mineralogy, *Silliman's Journal*, September, 1862, p. 206), and, indeed, is proved by the analyses giving no soda, which Dr. Lunge rightly rejects as having nothing to do with natroborocalcite—such being, in fact, analyses of the mineral species now distinguished as hayesine, and represented by the formula $CaO,2BO_3+6HO$.

I may mention, also, that in my paper of 1861 I proved the existence of a second hydrated borate of soda and lime, differing most distinctly in crystalline form and composition from natroborocalcite, very near the locality of which it was found associated with and sometimes characteristically imbedded in Glauber salt, which I called cryptomorphite. This mineral contains 59 per cent. of boracic acid, and does not seem to have been found with the other borates at Iquique and elsewhere, as the amount of boracic acid obtained on analysis is not sufficiently high to be accounted for by its unsuspected presence. On looking back to my notes of the first finding of natroborocalcite here, dated March 18, 1857, I find reason to believe that cryptomorphite was observed at the same time, but left unexamined. The facts noted are really very curious, as pointing to the possible existence of a mineral which is sometimes the parent of both the hydrated borates mentioned. What I find in my notebook is substantially the following :—

"I think it possible that the mineral (natroborocalcite) as it occurs in the silky needles is really a product of alteration by efflorescence of another. Dr. Harding showed me, among specimens like my own (rounded masses such as are found at Iquique), some groups of transparent crystals, perhaps rhombic, aggregated into mammiliated masses of about half an inch in diameter; he gave me a few, and in a day or two they had effloresced, and their surfaces being broken they seemed to have the silky lustre, while of the part remaining transparent a portion was found not to dissolve in water, but to separate into distinct, small, transparent (rhombic ?) [*sic*] crystals which speedily went up in hydrochloric acid. In other cases the efflorescence seems now going on, and on breaking crystals which originally were transparent in appearance, the silky needles are found in the interior. The finest specimen, which two days ago I saw altogether or almost entirely transparent, is now covered with opaque efflorescence, and I think the silky needles are quite obvious in the interior. Analysis showed the portions remaining transparent to be chiefly Glauber salt."

I conclude now from this note that the silky needles were natroborocalcite, and that the rhombic crystals, soluble not in water but in hydrochloric acid, were cryptomorphite, and that both minerals either were underlying Glauber salt, which alone effloresced, or were formed from a mineral of which this last was a large constituent. The natroborocalcite itself is, as above mentioned, also found here in rounded masses, exactly such as occur at Iquique; these are imbedded directly in gypsum, so as to leave no cavity whatever, and show an origin other than that possibly indicated in the note transcribed.

While on this subject I may as well correct a statement made by my friend Professor O. C. Marsh, of Yale College, which, if left unaltered now that the minerals in question are better understood, can only mislead. I refer to his giving ("Catalogue of Mineral Localities in Nova Scotia, &c.," *Silliman's Journal*, January, 1863) hayesine as one of the minerals found in the gypsum of Windsor; this species has never been met with here; the only borates found are natroborocalcite and cryptomorphite.

Analysis of a Fossiliferous Limestone containing a Magnesian Silicate, by J. WALLACE YOUNG.*

As the study of the metamorphism of rocks is daily gaining in importance, it may not be uninteresting at the present time to direct attention to an altered coralline limestone of carboniferous age, which was obtained from a quarry near Kircaldy, Fifeshire. The specimen was given me for examination by a geological friend, as he thought it contained something uncommon from the peculiar soapy feel which it possessed.

The limestone, if I may still so call it, is of a greyish colour, the imbedded corals—which are the *Lithodendron junceum* of Fleming—being a little lighter than the surrounding matrix. The corals were more distinctly observed when a few fragments were placed in dilute hydrochloric acid, to remove the carbonate of lime as much as possible; the structure, however, is hardly so well preserved as in the unaltered portions of the same limestone. As the powdered mineral was found to be only partially decomposed by HCl, even after prolonged contact, it was fused with alkaline carbonate, and the analysis carried out in the usual way for insoluble silicates. The water was estimated by direct weighing. The composition is as follows :—

Specific gravity at 15·5° C. 2·670.

	1.	2.
Silicic acid	39·91	60·59
Magnesia	22·05	33·47
Alumina and oxide of iron	2·42	3·67
Water	1·49	2 26
Carbonate of lime	34·08	
	99·95	

No. 1 is the mineral as a whole. No. 2 is the centesimal composition after deducting the carbonate of lime; it will be observed that this approaches closely to the composition of ordinary steatite. Dilute acetic acid removed carbonate of lime only; the residue did not effervesce with concentrated HCl, and contained no lime: the magnesia, therefore, existed entirely as silicate, and the lime as carbonate. The metamorphism which this limestone has undergone must of course have taken place in the wet way. The magnesian silicate which has thus displaced the carbonate of lime, may, perhaps, have been derived from the decomposition of some of the greenstone rocks, which are, I understand, found in this locality; but I throw this out only as a conjecture.

Being favoured with some small specimens of the limestone from other parts of the same quarry, I

* Communicated by the author.

examined them for magnesia, but only found very small quantities. Some pieces were crystalline, and dark in colour from the presence of organic matter, the corals being almost quite white. On subjecting fragments to the action of dilute HCl, small portions of the corals were left undissolved, as delicate white tubes, which were found to consist principally of silicic acid and lime, with a little magnesia and alumina.

Other portions of the limestone similarly treated with acid left 2 or 3 per cent. of an insoluble residue, consisting of silicic acid and alumina, with small quantities of lime and magnesia. These pieces differed entirely, therefore, from that first analysed.

Glasgow.

On the Preparation of Pure Chloride of Ammonium, by Professor J. Stas.

I. Chloride of Ammonium from the Ammonia extracted from Sal Ammoniac, purified by Aqua Regia.—Ten litres of a boiling saturated solution of sal ammoniac were added to a litre of nitric acid of specific gravity of 1·4. The liquid was kept boiling as long as it gave off chlorine. The sal ammoniac which separated from the liquid on cooling was dissolved in pure boiling water, and the solution was boiled with a twentieth of its volume of nitric acid as long as chlorine was produced. The liquid, diluted with pure water until it no longer deposited chloride on cooling, was poured upon hydrate of calcium contained in a large retort to set free the ammonia. The latter, first washed in water, was then placed into pure water. The ammoniacal solution produced was in its turn nearly saturated by a current of pure hydrochloric acid.

The chloride of ammonium, which was deposited by the liquid after its concentration and cooling, was dried at 100° by passing continuously a current of ammoniacal gas into the long-necked globe in which it was being dried. This being done, I sublimed the sal ammoniac with the least possible elevation of temperature, keeping the neck of the globe as far as possible full of dry ammoniacal gas.

The chloride volatilised without leaving the least trace of carbon—a proof that the sal ammoniac contained no compound ammonia. However, it was easy to perceive that the bottom of the globe, which was of ordinary glass, was very slightly attacked. On breaking it to detach the sublimed chloride, I found, in fact, that traces of chlorides of sodium and calcium were formed at the expense of the substance of the glass, and that some silica was set free. By means of spectrum analysis I found that the sublimed sal ammoniac, which was quite colourless and remarkably transparent, contained traces of sodium, but it was absolutely free from calcium.

In order to eliminate the traces of sodic chloride, which were carried over with the vapour of the sal ammoniac, I sublimed it two more times in an atmosphere of ammonia, at the lowest possible temperature, devoting to this operation some *hard glass* vessels that I had had made expressly for the transformation of the alkaline chlorides into nitrates of these metals. At the temperature at which the chloride of ammonium was sublimed these vessels resisted its vapour perfectly. In the notice "*On the Transformation of the Chlorides into Nitrates*," I give the composition of the glass of these vessels.

The chloride of ammonium, before being employed in this determination, was heated, in the same vessel in which it was weighed, up to the point of giving off vapour, so as to drive off the condensed ammonia.

II. Chloride of Ammonium produced by means of Ammonia prepared from the Commercial Sulphate.—To prepare chloride of ammonium by means of ammonia, from commercial sulphate, I first treated the latter compound as follows:—Two kilogrammes of sulphate were heated with a kilogramme and a half of concentrated sulphuric acid up to the temperature at which the sulphate begins to decompose with effervescence. I then introduced nitric acid by degrees into the mixture until the liquid, which was of a tolerably strong blackish-brown colour, had become quite colourless. The compound ammonias and organic matters contained in the sulphate are thus completely destroyed, with liberation of carbonic anhydride.

The acid sulphate, suitably cooled, was poured into about ten times its volume of cold water, and the excess of acid nearly saturated by lime water. When the sulphate of calcium was deposited, the supernatant liquid was mixed with a sufficient excess of slaked lime contained in a very large globe, and was heated in a bath of a saturated solution of common salt, so as to drive off the ammonia it contained. The latter, after washing in water, was put into pure water.

The ammonia, when dissolved, was saturated by a current of pure hydrochloric acid. The solution of sal ammoniac produced was evaporated to dryness in a globe of *hard glass*, and the residue was sublimed in an atmosphere of ammonia obtained from part of the same chloride.

The sal ammoniac volatilised without leaving a trace of a residue. The sublimed product was absolutely colourless; it gave off an ammoniacal smell. Before being employed it was heated until vapour was given off, so as to drive off the condensed ammonia.

The Reducing Properties of Zinc, by M. Stahlschmidt*—*Preparation of Nitrites, by M.* Erdmann.†

M. Schönbein has shown that alkaline nitrates, in solution in water, are partially reduced to nitrites, when a zinc or cadmium wire is plunged into them. This reaction, which is naturally slow, may be accelerated until it is available as a method of preparation.

For this purpose M. Stahlschmidt uses powdered zinc, especially the residue of manufacture, used as a colour, and known as *gris de zinc*, and which should be previously treated by a little diluted sulphuric or hydrochloric acid, until a disengagement of hydrogen takes place. By this means the oxide and carbonate of zinc are eliminated, the other metals remaining intact.

The reduction of nitre is effected, especially when hot, to the point of disengaging ammonia, from which moment the production of nitrite takes place rapidly.‡ Upon this fact the author has built the following process of preparation, in which free ammonia plays a part:—

Take a solution of saltpetre saturated at 30 or 40° C., add a tenth of its volume of ammonia, and a certain quantity of powdered zinc. Shake and cool the liquid from time to time to prevent its becoming heated above 50° C., add more zinc, and continue the treatment while any saltpetre remains.§

* *Ann. Physik und Chem.* cxxviii. 467.

† *Journ. prakt. Chem.* xcvii. 388.

‡ To ascertain the presence of nitrate in the nitrite, take a little of the solution and expel the ammonia by boiling; decant, and add alcohol (about three or four times the volume). If there is much nitrate, a crystalline precipitate will be obtained; if not, only a turbidity will be produced.

§ If there be an excess of saltpetre and zinc, the reaction becomes energetic, and caustic potash and free nitrogen are formed. This resembles the action of the amalgam of sodium, which, according to M. de Wilde, produces analogous effects.

When it has nearly disappeared, cool, decant, and then boil the liquid to expel ammonia, and filter to separate the oxide of zinc. The liquid will retain small quantities of zinc; add a little carbonate of potash, then pass a current of carbonic gas, and zinc and cadmium will be precipitated. Then neutralise by weak nitric acid, after which the nitrite and nitrate of potash may be separated by crystallisation.

The process proposed by M. Erdmann is founded on an analogous reaction. It consists in keeping in melted saltpetre several times its weight of iron filings or turnings. Decant the salt when it may be supposed to be sufficiently rich in nitrite, and recharge the crucible. Then dissolve and concentrate it so as to separate by crystallisation the nitrate which has escaped reduction, and neutralise by nitrous gas prepared with starch and nitric acid.‖

Gris de zinc reduces nitric ether in the same way; it reduces iodates into iodides, turns red prussiate yellow, and decolours indigo.

It has no action on chlorates; it attacks sulphides, and in some respects behaves like oxide of copper—for instance, it rapidly converts sulphide of barium into hydrated baryta, itself turning into sulphide of zinc.

TECHNICAL CHEMISTRY.

On the Use of a Tin Bath in the Fabrication of Lighting Gas from Liquid Hydrocarbons, by M. Riaton.

The inventor states that in the manufacture of lighting-gas from liquid hydrocarbons the hydrocarbons must be at a very high temperature, but the gas must be exposed to this as little as possible.

In the ordinary process the hydrocarbon is made to fall drop by drop in a red-hot retort. It instantly forms a deposit of carbon, which intercepts the heat, and can only vaporise the drops which come after.

If a bath of melted tin be placed in the bottom of the boiler, so that each drop falls upon the red-hot metal, the gas escapes, a deposit of carbon forms and lowers the temperature of the bath. This repeated difference of temperature between the upper and lower parts of the bath causes constant movement, which, by a particular arrangement, causes the carbon to accumulate between the pipe conducting in the hydrocarbon and the sides of the retort; it is removed through a lateral orifice. The gas must be immediately drawn off by an aspirator.

PHARMACY, TOXICOLOGY, &c.

The New Pharmacopœia (1867).

[THIRD NOTICE.]

The list given in the text of the substances the names of which have been altered, calls for much commendation, but is also liable in many cases to the charge of want of consistency. Brevity is not recognised now, as hitherto, as the test of rigid accuracy. All the vegetable substances have appended to them a mention of the part of the plant officinal; thus, Rosæ caninæ fructus, Rosæ centifoliæ petala, Rosæ gallicæ petala, replace respectively Rosa canina, Rosa centifolia, Rosa gallica. This change is a sweeping one, but the expediency of it will be doubted by no one. By this general expression the part of the plant will always be borne in mind; formerly the part of the plant only was mentioned when two or more parts of the same plant were officinal—one used for one preparation, the other for another, as was the case with conium, when leaves and fruits were used.

It was recognised as a principle in the last edition that the patient should know what drug he was taking from the prescription, the diminished chances of poisoning by mistakes of the druggist being supposed to more than counterbalance the harm possibly effected by the fears of the patient at taking strong remedies. Upon this principle were framed the expressions—Hydrargyri corrosivum sublimatum, Calomelas, Pilula opii, Pulvis kino cum opio, &c.

The editors of the present edition take just the opposite view of the question, and to the foregoing substances give the following names:—Hydrargyri perchloridum, Hydrargyri subchloridum, Pilula saponis, Pulvis kino compositus, &c., each for each.

Now, this is altogether a matter of opinion, and everybody has his own views on the subject; for our part we think that the late plan was the most straightforward, and was not open to a sort of lurking suspicion of mystification about it. Why should an opium pill be called Pilula saponis, soap being only a basis, and a basis, too, of so many preparations of the kind? If adopted at all, the idea should, we think, be exhausted; for the consistency of the thing, would it not be better to call liquor strychniæ, *liquor innocuus*, and liquor arsenicalis, *aqua Toffanæ?* The fears of patients would not then be aroused by knowing that they were taking arsenic and strychnia.

The expression of the old British Pharmacopœia, Ferrocyanide of potassium, seemed to us to be beyond all criticism for preparing hydrocyanic acid; its name has, however, been altered to Potassæ prussias flava. We should have thought that prussias would have sounded dangerous to the Pharmacopœia Committee as being too suggestive of prussic acid. So now hydrocyanic acid is prepared from prussiate of potash, the latter of which, however, does not appear in prescriptions. We have noticed that an enlargement of phrase is given to some substances. Confusion results in many cases: thus, the late Ferri peroxidum hydratum is now called Ferri peroxid. humid., and in the new book Ferri peroxidum hydratum is used for the late Ferri peroxidum.

The old sulphuret is extinct now; for Antimonii sulphuretum, read Antimonium nigrum.

The names of many salts are altered, but without the slightest method traceable. (1) In some cases a scientific name replaces a pharmaceutical one; in others (2) just the opposite—

(1) Brit. Pharm., 1867.	Brit. Pharm., 1864.
Bismuthi subnitras	Bismuthum album
Plumbi oxidum	Lithargyrum
(2) Brit. Pharm., 1867.	Brit. Pharm., 1864.
Soda tartarata	Sodæ et potassæ tartras
Unguent. zinci	Ung. zinci oxidi

The substances remaining the same. Further, there may be some reasons for the following, which are not obvious:—

Brit. Pharm., 1867.	Brit. Pharm., 1864.
Ammonii chloridum	Ammoniæ hydrochloras
Potassæ prussias flava	Potassii ferrocyanidum.

The new nomenclature is not in every case consistent the influence of the bad notation is detected in it.

‖ Former observations have ascertained that this gas gives very little nitrite; however, it neutralises alkaline liquid, and that by forming nitric acid. The object would then be more rapidly obtained by neutralising with this acid, which, after all, introduces no new element into the liquid. For the application of these principles see *Annuaire de Chimie*, 1849, p. 102.

As was before said, the names of compounds are given in Latin. Pharmacy Latin is not altogether beyond criticism when applied to chemical substances with English names; for by the rule that gives Iodum and Chlorum for Iodine and Chlorine, Glycerine should be Glycerum, whereas the series of compounds before alluded to are called Glycerina. The latter term, as applied to a mixture of glycerine and water with some acid, is, to say the least, awkward-looking. Old mistakes in this department have been again overlooked, for is not the strength of spiritus *rosmarini* diminished one-fifth? Horace (an amateur physician, by the way), had he lived till now, would doubtless have seen just reason for writing to Phidylo in more modern Latin—not to Phidyle as

> "Parvos coronantem *marino*
> *Rore* Deos, fragilique myrto."

But the pharmacist must not be deprived of his Latin on any consideration.

Chemical substances appearing for the first time in a national Pharmacopœia are numerous, and very justly introduced. The first on the list is Acidum carbolicum; then there is the Sulphate of atropia, followed by Bismuthi carbonas, Bismuthi et ammoniæ citratis liquor, Cadmii iodidum, Cerii oxalas, Ammoniæ citras, Arsenici hydrochloras, Morphiæ acetas; among the liquors, effervescing liquors of Lithia, Soda, and Potash; Sulphuris iodidum is restored from the London Pharmacopœia, Acetate of iron in a tincture from the last Dublin one.

PHYSICAL SCIENCE.

Action of the Induction Spark on some Gaseous Hydrocarbons, by M. P. DE WILDE.

Acetylene.—Introduce the dry gas into a small eudiometer over mercury, and furnished with two platinum wires about 4 millimetres apart. At the passage of the spark, a light tuft of carbon is formed between the wires, and the action stops. Agitate the eudiometer, so as to cause the mercury to knock off the carbon, and the sparks which again pass will reproduce this phenomenon. The eudiometer is shaken as often as necessary for the continuation of the experiment. If operating with 10 cubic centimetres of gas, from fifteen to twenty agitations will suffice; the experiment will then proceed uninterruptedly. In ten or fifteen hours all the acetylene will be decomposed. The remaining gas submitted to eudiometric analysis is found to be hydrogen. The acetylene should give its volume of hydrogen, but there is always a diminution of about a fifth, which, may, perhaps, be attributed to the absorption of hydrogen by the deposited carbon, or, perhaps, to the formation of some trace of condensed hydrocarbons. The result of this experiment is, that acetylene decomposes into its elements under the influence of the induction spark.—*Bulletin de la Société Chimique de Paris*, vi. 267.

Uses of Sulphate of Magnesia.—A strong solution of sulphate of magnesia mixed with whitewash will produce a beautiful white for ceilings of rooms in houses. It will, if used in the same way, be found useful for rifle targets. A small quantity of this salt used along with starch adds considerably to its stiffening powers, and renders the articles to a certain degree fireproof.

FOREIGN SCIENCE.

(From our own Correspondent.)

Paris, April 16, 1867.

The unexpected observation of the *Lycoperdon giganteum* has led M. Ernest Baudrimont to some very interesting conclusions. Fourteen days after its apparition at the surface of the ground it had acquired a considerable size. Plucked on September 17, 1866, when it commenced to decrease visibly, it was nearly of a regular spheroidal form, with a very short peduncle of a very beautiful white colour, dull, and slightly rosy; the skin was distended, and elastic under the pressure of the finger; its circumference measured 1 m. 4 c. on its greatest diameter, the weight being 3 kilo. 500 grammes. When detached circularly by means of a sharp instrument, a great quantity of turbid liquid was disengaged of a greenish-yellow colour. It was placed immediately in a baking-oven, where it remained twenty days. Taken out completely dried, it weighed 305 grammes, thus showing that before desiccation it contained 91·28 per cent. of water. Analysis has proved that nitrogen gas represented alone 8·96 per cent. of the weight of the dried fungus, or 0·78 per cent. of the weight of it in its normal state. If we suppose all this nitrogen to have been in the state of albumen, a substance which contains 17·70 per cent. of nitrogen and 53 per cent. of carbon, the total mass of lycoperdon (305 grammes) contains 174·063 grammes of carbon; we have even 142 grammes by adding the carbon contained in the non-nitrogenised substances, its cellulose, &c. This being ascertained, we have 142 grammes of carbon representing 520·66 grammes, or 265 litres of carbonic acid, and thence 530,000 litres of air. It is from this enormous volume of air, which is about equal to a cube of 8 metres linear edge each way, that the fungus in question must have drawn, without losing a single trace, and, if we may so term it, with mathematical precision, the 142 grammes of carbon necessary for its development of fourteen days. This is at the rate of, per day of twenty-four hours, 10·15 grammes of carbon, 18·9 litres of carbonic acid gas, and 37·800 litres of air. At 86,400 seconds per day, it is upon nearly half a litre of air that the plant must have operated per second to effect the total extraction of the carbonic acid gas which was in it. By what means can we estimate the prodigious activity that this inferior plant could develope to be able to take in fourteen days all the carbonic acid belonging to 530,000 litres of air? How astonishing, then, must be the delicacy of the absorptive organs which seize on its flight an elastic fluid—if we may so call it—intangible, disseminated in such an enormous mass, continually moving with great rapidity! But this is not all. The mean circumference of the fungus was 0·990 m.; the radius, 0·157 m.; its volume more than sixteen millions of cubic millimetres; and its mass formed of cellules 1 millimetre long at most, and the $\frac{1}{500}$th of a millimetre in thickness, between which are placed the reproductive spores. The total number of the cellules exceeds fourteen billions (14,589,140,400); and since the development lasted fourteen days, a million of cellules had to be produced every four hours—twelve thousand cellules per second! Just let one stroke of the pendulum, and then another, be heard, and conceive, if you can, that in that space of time the fungus constructed 12,000 cellules, besides (as the spores are a hundred times at least more numerous than the cellules) 1,200,000 spores, without any sensible shock or any hurried interior derangement capable of disturbing the mysterious equilibrium that reigns through all the parts of this living body. How great, then, is the prodigious energy which animates the material substance, and which can accommodate itself instantaneously to the exigencies of life!

F. Moigno.

UNIVERSAL PARIS EXHIBITION OF 1867.

(From our Special Correspondent.)

Class 44. *Chemical and Pharmaceutical Products.*—We commence our description of the Exhibition with that of the department most calculated to interest the readers of the Chemical News. The industrial development of chemical products is one of the greatest importance—the more so, as it furnishes other arts with substances indispensable to their very *existence*. The production of chemical products, in France alone, represents a sum of forty-eight millions sterling. Sulphuric acid, soda, soap, india-rubber articles, and stearine candles, figure for half that sum; and, if we add the value of the dyeing materials, the reagents employed in bleaching, the manufacture of paper, painting, glass-blowing, calico printing, manures, the galvano-plastic arts, photography, gilding, the silvering of metals, &c., the 48,000,000*l.* will be easily accounted for, and perhaps exceeded. Already, in 1863, the exportation of chemical products by France amounted to 2,120,000*l.*

The chemical exhibition of 1867 is remarkably fine, and quite completed as far as regards the French section, the most advanced of all. There are no less than 358 French exhibitors; to which must be added, 44 Algerians, 40 Hollanders, 1 Luxembourgese, 85 Belgians, 125 Prussians, 17 Hessians, 7 Baden, 15 Wurtemberg, 15 Bavarians, 150 Austrians, 37 Swiss, 57 Spaniards, 16 Portuguese, 71 Russians, 2 Chinese, 1 Tunis, 30 Americans, 98 Brazilians, 2 Egyptians, 108 English, 199 Italians, 1 Pontifical, 98 Turks, 5 American Republics.

The most salient progresses accomplished since 1862 are the invention of new colouring matters obtained by toluidine and methyl-aniline, the transformation of naphthaline into benzoic acid, the industrial production of magnesium, &c.

The manufacture of stearine, originated in France, and there for the first time applied practically, can, in spite of the import duties and other taxes, compete advantageously with any other market. The good quality and the reasonable price of the candles enable the French manufacturers to maintain advantageously their ground against all competition, so that the exportation is very considerable; while the price of stearic acid of the first quality is only 1 fr. 70 c. per 100 kilos. (220 lbs.). Notwithstanding the elevated price of the original materials, the exhibition of this product holds a prominent place at the Palace in the Champ de Mars. M. de Milly, so ably assisted by his son-in-law, M. Bouis, a distinguished chemist, has made an extraordinary progress in this branch of manufacture. He suppresses the distillation of fatty matters; he treats the tallow with sulphuric acid at 55° C., and obtains a black mass, which he submits to a first pressure by hydraulic machine. The mass is by this considerably discoloured, and is of a dark yellowish-grey colour. It is then compressed a second time, by which all the oleic acid is expelled; the remaining substance is left as white as snow, and can serve at once for the manufacture of wax candles of the first quality. This result has occupied the attention of chemists and manufacturers as one of the greatest importance. M. de Milly exhibits at the same time two sorts of soap manufactured with oleic acid of the first and second pressure; they differ considerably in shade.

The glass cases of the other French exhibitors, which contain the excellent products of MM. Leroy and Durand of Gentilly, M. Venigue of Ivry, Cresenberge of Clichy, Fournier of Marseilles, Belhommet de Landernau, are admirably classified, but we do not know at present what they contain new. MM. Morani Brothers exhibit in a pavilion of the park in the French quarter, near the Pont d'Jena, all the necessary machinery for the manufacture of stearine, and set it at work every day.

One of the great novelties of 1867 is the process of the conversion of nodules of phosphate of lime into phosphate of iron, and the decomposition by the latter thus obtained of sulphates of soda and potash, to obtain tribasic phosphates of soda and potash. Discovered by M. Boblique, and applied on a large scale at the Javelle chemical works under the direction of M. Fourcade, this process has now been brought to perfection. The nodules of Ardennes contain, on an average, silica 34·50, lime 27·80, phosphoric acid 19·30, phosphorus 8·60, and other matters.

To a hundred kilos. of nodules are added sixty kilos. of iron ore, which is found nearly always at a short distance from the beds of the nodules or coprolites, and of which the composition is peroxide of iron 35·43, iron 24·80, water 6·46, siliceous or chlorite gangue 18·11. The mixture is melted in a blast furnace, and the results obtained are—1. Phosphate of lime containing on an average 20 per cent. of phosphorus. 2. Slag, containing silica 54, lime 32, alumina and magnesia 14. In order to manufacture the phosphate of soda a mixture of 100 parts of powdered phosphorus, 200 of crushed sulphate of soda, and 30 parts of fine charcoal are fused together; they are well stirred up during the fusion. Afterwards, when the reaction has taken place and the mass has become fluid, it is cast in blocks of 600 to 650 kilos. Exposed to the air for a few days it crumbles into a sort of dust, and it is afterwards submitted to a regular process of washing, by means of which are produced abundant crystals of tribasic phosphate of soda, represented by $3NaO,PO_5$. The insoluble residue is a double sulphide of iron and sodium Fe_4NaS_3, which, when roasted in a pyrites furnace, gives sulphurous acid to be transformed into sulphuric in leaden chambers; the residue is peroxide of iron mixed with sulphate of soda, which is separated by a new washing. This is evidently a complete process, in which the same sulphur and the same iron can serve indefinitely.

The phosphuret of iron and the phosphates of potash and soda resulting therefrom figure for the first time in the showcase, No. 215, of M. Fourcade, of the Quai de Javelle.

Side by side we have MM. Perret and Olivier, owners of the Saint-Bell and Chesy mines, so rich in sulphurets of iron and copper. These exhibitors have written in gilt letters on their glass case that they burn or export annually 70,000 tons of pyrites, and that the capacity of their leaden chambers amounts to no less than 40,000 cubic metres. In 1855 there was already a complaint as to the want of sulphur and its elevated price; they were one of the first to point out to the manufacturers of sulphuric acid the pyrites supply of M. Perret; they also were the first to propose the substitution of pyrites for sulphur, when, as at Newcastle, copper is extracted from the residues of the roasting.

After having mentioned these chemical items, we now turn to those of pharmacy. In the first ranks of the exhibitors of this section we must place M. Adrien, the able collaborateur of M. Jules Regnaud, Director of the Central School of Pharmacy, who has so well fulfilled the delicate mission of fabricating pure chemical products according to strictly established formulæ. His opium of Smyrna (a sort of mixture of all sorts of commercial opium), containing 10 per cent. of morphia, is much sought for, especially in the preparation of the medicines of the Codex in use in France. We may cite among some remarkable products, scammony containing 15 per cent. of pure resin.

(From another Correspondent.)

You are so accustomed in England to mercilessly criticise men in office, and your men in office are so accustomed to abuse in the public prints, that no amount of it causes any sensation. Even the persistent abuse of "Cole, C.B.," by the *Saturday Review*, has not excited attention, nor has it, that I am aware of, been neutralised by anything approaching to a fair public announcement of what we all appre-

ciate here—namely, his unceasing efforts to render the English part of the Exhibition worthy of the nation.

The chemical portion is by no means rich in new products. It is evident that the discovery of aniline colours has, in some respects, been detrimental to the progress of science. Do not misunderstand me. Of course, I am filled with admiration of the beautiful results which have rewarded the labours of so many chemists with new and gorgeous colouring matters, but it is plain that, in the pursuit of wealth, so many young and energetic chemists have devoted themselves to the study of aniline and its derivatives, that other, and perhaps as rich, fields of study have been neglected.

But if the visitor is struck by this deficiency in absolutely new substances, he is no less impressed by the magnificence and purity of the specimens exhibited. Among the novelties I observed the new blue discovered by MM. Girard and De Laire. These ingenious young chemists prepare their colouring matter by the action of sesquichloride of carbon on diphenylamine. I will give you a full account of this and other novelties in a subsequent letter.

Your readers will be sorry to hear that comments are being continually made upon the fact, that while the Germans come out in great force with dyes and colouring matters, the great English houses, whose cases at the last English Exhibition were among the most brilliant objects in the building, are wholly unrepresented. This is greatly to be regretted, as the true reasons for it will probably not be guessed at. One is continually astonished by the low prices at which the new dyes are now produced. When the complication of the processes by which they are produced is considered, it would really appear as if the profits upon their manufacture can now be little more than are obtained from the commonest chemicals. It is evident that manufacturing processes generally have been both improved and simplified, and it is to be hoped that the fall in prices is due more to those causes than to overproduction.

The natural alkaloids and the new metals are among the chemical substances which divide with colouring matters the attention of the visitors.

Most of the scientific celebrities of Europe are now in Paris, and may daily be seen studying the beauties and curiosities of the Exhibition. The jury is also in full work preparing for the awards, which we doubt not will afford the usual amount of envy, hatred, and malice.

It is unnecessary, perhaps, to tell you that the department we are considering is very unequal in interest. In a corner where it can scarcely be seen will be found a ridiculously small case containing almost priceless chemical rarities, while within a yard will be found one of six times the size devoted to the exhibition of nostrums which owe their notoriety solely to the unblushing impudence with which they are puffed.

In my next I hope to be able to give an account of some of the chemical rarities and the processes by which they are obtained.

NOTICES OF BOOKS.

A Plea for Reflectors: being a Description of the New Astronomical Telescopes with Silvered-Glass Specula, and Instructions for adjusting and using them. By John Browning, F.R.A.S., F.M.S., and F.M.S.L. London: William Francis. 1867.

The author has written this pamphlet with a view to counteract the general prejudice against the employment of reflectors in telescopes; the relative merits of refractors and reflectors are impartially described, and diagrams given of the best forms of apparatus. The whole forms a very useful work, and one which amateur astronomers would do well to consult before deciding upon what instrument to procure.

Mr. Browning begins by stating the advantages reflecting telescopes possess over refracting ones. He then describes the disadvantages that formerly led to their being almost totally discarded, and the improvements by which these defects have been remedied; and, finally, there is a description of the various forms and sizes of reflecting telescopes, and the mode of using them. The advantages of this form of instrument seem so great, and, in large sizes, the difference of price, as compared with achromatic telescopes, is so enormous, that we should think that nothing but ignorance of its merits has prevented its very general adoption by astronomers. The following, according to Mr. Browning, are the most important advantages of the best forms of reflectors:—

"They are only half the length of achromatics of the same aperture.

"Their dividing power, on many stars, is superior to that of achromatics, aperture for aperture, as they give smaller discs; and on the moon and planets their performance cannot be surpassed.

"They are quite free from the aberration of colour.

"When viewing objects in the best position for observation—that is, between the zenith and 45° above the horizon—they are much more convenient to use than refractors, because the eye-piece of the reflector remains nearly horizontal; a refractor, under the same circumstances, necessitates the observer's almost lying down on his back. Micrometric measurements may be obtained with great exactitude, from the easy position of the observer.

"The price of the specula in small sizes is only about one-fifth, and, in large sizes, only one-tenth, of that charged for good achromatic object-glasses of the same aperture.

"For instruments of equal power the new reflecting telescopes do not require an observatory half the size that would be necessary for a refractor, and a building half the size would not be one quarter the expense."

The telescopes here described are of the Newtonian form, which is thus described:—

"The Newtonian telescope consists of a tube closed at the lower end, which is occupied by a concave mirror. The cone of rays reflected from this mirror is again reflected at right angles from the surface of a small plane mirror, mounted at an angle of 45° near the open end of the tube, into the eye-piece, which is exactly opposite.

The defects which led to reflectors being so long disused were as follows:—

The alloy of which the reflectors were made was so brittle as to break sometimes by a sudden change of temperature.

Their great weight made them difficult to mount firmly.

Their surface rapidly tarnished, and could not be restored except at great expense and the risk of irretrievably injuring the mirror.

In the telescopes made by the author, and described in this pamphlet, the mirror is of glass, coated with pure silver by Liebig's process, which form has the following advantages:—

"These glass mirrors are not at all injuriously affected by change of temperature, and their lightness very considerably reduces their liability to flexure; indeed, mounted in the manner I shall presently describe, no flexure has ever been observed in them. I may, however, state that I make the discs of the specula, which Mr. With parabolises for me, out of glass nearly twice the substance of that generally used for the purpose. The coating of pure silver reflects fully one-third more light than the best speculum metal, as the alloy before mentioned is called. But the greatest superiority of silvered glass over metallic mirrors consists in the fact that should they become tarnished, their brilliancy may readily be restored by gentle friction with soft leather, and a little of the finest rouge; and even

should the silver coating become utterly spoiled, it may be easily removed without in any way impairing either the figure or polish of the glass speculum, and a fresh one deposited at a trifling cost, thus making the mirror equal to new; and this may be repeated indefinitely. Should the owner possess a little patience, he may renew the coating himself at the cost of only a few pence. The silvering process is fully described in an appendix."

The remainder of the pamphlet is devoted to a description of the various instruments supplied by Mr. Browning, and is fully illustrated. A frontispiece shows Saturn, as seen in a 13-inch metallic reflector, and Mars, as seen in an 8½-inch reflector.

CONTEMPORARY SCIENTIFIC PRESS.

Under this heading it is intended to give the titles of all the chemical papers which are published in the principal scientific periodicals of the Continent. Articles which are merely reprints or abstracts of papers already noticed will be omitted. Abstracts of the more important papers here announced will appear in future numbers of the Chemical News.]

Annales du Génie Civil. February, 1867.

De Kappelin "*On the Use of Annatto for Dyeing and Calico Printing.*"—A. Ortolan: "*Some Practical Remarks on Boiler Explosions.*"—"*Instructions for fixing Lightning Conductors to Powder Magazines, drawn up by a Commission of the French Academy of Sciences.*"—Limet "*On a Specimen of Boiler Scale.*"—Simonin "*On the Coal Formations and Metallic Veins of the Old and New World.*"—J. Roth "*On the Composition and Adulteration of the Crude Tartar of Alsace.*"—Rousseau: "*An Improvement in the Manufacture of Beetroot Sugar.*"—Junemann, Du Rieux, and Rottger, "*On the Use of Strontia in the Manufacture of Sugar.*"—Clémandot: "*A new Silica Glaze for Pottery Ware.*"—Bourne: "*A Method of Deodorising Vulcanised India-rubber.*"—Corduré: "*A Method of obtaining Silver from Argentiferous Lead.*"—Bellouhey: "*A new Process for Enamelling Iron.*"

Technologiste. February, 1867.

Wagner "*On the Manufacture of Nitric Acid.*"—C. F. Richter "*On the Preparation of Acetic Acid and Acetates from Pyroligneous Acid by means of Baryta.*"—L. Knaffl "*On the Preparation of pure Cyanide of Potassium.*"—C. Dieterich "*On the Preparation of Chrome Green.*"—J. C. Fischer: "*Historical and Practical Researches on the Nature of Purple of Cassius.*"

Annalen der Chemie und Pharmacie. February, 1867.

R. Fittig: "*Researches on Mesitylene;*" "*On Ditolyl, a new Compound Isomeric with Dibenzyl, being a Supplement to the preceding Memoir.*"—C. Bigot and R. Fittig "*On the Synthesis of some new Hydrocarbons.*"—J. Roesler "*On some Chromicyanogen Compounds.*"—S. Cannizzaro "*On Brominated Toluol.*"—L. Swiontkowski "*On the Behaviour of Solutions of Permanganate of Potash towards Peroxide of Hydrogen.*"—A. Mühlhauser "*On the Action of Cyanide of Potassium on Binitronaphthalene.*"—A. Claus "*On the Action of Iodide of Ethyl and Zinc on Sulphuric Ether.*"—A. Lieben "*On the Synthesis of Alcohols by means of Chlorinated Ether.*"—A. Ladenburg "*On the Synthesis of Anisic Acid and of one of its Homologues.*"—A. Ladenburg and A. Fitz "*On some Derivatives of Paroxybenzoic Acid.*"—A. Tenner "*On the Presence of Salt in Extract of Meat.*"—C. Huber: "*Preliminary Note on some Derivatives of Nicotine.*"—A. Baeyer "*On Mellitic Acid.*"

Archives des Sciences. January, 1867.

J. C. Marignac "*On some Fluorides of Antimony and Arsenic.*"—J. Plateau: "*Seventh Series of Experimental and Theoretical Researches on the Equilibrium Figures of a Liquid Mass without Weight.*"—"*Note on an Earthquake which occurred in Algeria at the beginning of the year 1867.*"—A. Secchi "*On the Origin of the Air Lines of the Solar Spectrum.*"—A. Mousson "*On the Ebullition of a Liquid when in Rotatory Motion.*"

Kunst und Gewerbeblatt. January, 1867.

J. Bergsmann "*On a Method of determining accurately the Melting Point of Fats.*"—"*On the Industrial Applications of and Trade in Ivory.*"—Wegler "*On the Relative Cost of Manufacturing Ice by Carré's and Siebe's Machines.*"—C. Puscher: "*A Solution for Etching Copper.*"—J. Stinde "*On Non-Explosive Glycerine.*"—G. Dachauer "*On Blue Transfer Paper.*"—"*On the Use of Oleic Acid in the Manufacture of Soap.*"—"*On the Action of Water on Lead.*"—"*On the Presence of Bisulphide of Carbon in Petroleum and Benzol.*"

NOTICES OF PATENTS.

Communicated by Mr. Vaughan, F.C.S., Patent Agent, 54, Chancery Lane, W. C.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

391. Sir J. Y. Simpson, Bart., Queen-street, Edinburgh, N.B., "Improvements in the utilising of mineral and other oils for the production of heat, and for illuminating purposes."—Petition recorded February 12, 1867.

721. J. Hamilton, Glasgow, N.B., "An improved artificial material for producing gas to be used for illuminating purposes."

728. B. Platt, Liverpool, "Improvements in and apparatus for the manufacture of chloride of lime."—March 13, 1867.

737. W. G. Blagden, Hackney Wick, Middlesex, "Improvements in extracting silver from alloys of zinc with lead." A communication from F. Marquez Millan, Rue Liandier, Marseilles, France.—March 14, 1867.

744. J. R. Parkinson, Blackburn, Lancashire, "An improved varnish or composition to be applied to healds of looms for weaving, and for other similar uses."

752. G. Smith, Headingley, Leeds, Yorkshire, "Improvements in the preparation of soap adapted more especially for the scouring of wool and woollen yarns."—March 15, 1867.

766. J. Hickisson, Southgate Road, Middlesex, "An improved preparation of biscuit and other pastry and bread."—March 16, 1867.

788. A. H. Hart, Gresham Street, London, and W. Parry, Birmingham, "Improvements in treating or purifying sewage, and in apparatus to be used for that purpose."

789. C. Allhusen, Newcastle-upon-Tyne, "An improved mode of treating small pyrites, and pyrites' dust, so as to obtain sulphur therefrom."—March 19, 1867.

810. G. Bischof, jun., Poppelsdorfer Allée, Bonn, Prussia, "Improvements in coating metals, and in apparatus employed therein and for like purposes."—March 20, 1867.

814. G. E. Marchisio, M.D., Baker Street, Middlesex, "Improvements in the preparation and application of isolating compositions for the protection of metallic surfaces from oxidation, and for the preservation of wood and other materials, and in the preparation of the residue of vegetable oils to be employed for such purposes."—March 21, 1867.

Notices to Proceed.

3093. J. Mitchell, Musselburgh, Midlothian, and W. C. Laird, Leith, Midlothian, "A new or improved detergent material applicable to the cleansing of wool and other fibrous substances, and to all purposes where coarse soap is used."

3097. J. K. Leather, St. Helen's, Lancashire, "Improvements in the manufacture of salts of soda and potash."—Petitions recorded November 24, 1866.

3165. S. J. Browning, Portsmouth, "Improvements in the method of applying and arranging apparatus for distilling sea-water, and also in the mode or method of combining and using such apparatus for that and other purposes."—December 1, 1866.

CORRESPONDENCE.

Ozone.

To the Editor of the Chemical News.

Sir,—During the first three months of the present year, the more salient points in the development of ozone were as follows:—

In January there were two well-marked periods of scarcely a trace of ozone—namely, from the 1st to the 5th, culminating on the 4th, when the test was colourless, and from the 10th to the 19th, culminating on the 13th, 14th, and 18th.

Both these periods were followed by equally well-marked periods of a large development of ozone. In February no such well-marked and settled periods occurred. On some days there was but little ozone, as, for instance, on the 2nd, and the afternoons of the 21st and 28th, especially on the afternoon of the 21st; while on other days there was a good deal, as on the 16th, 18th, and 20th. But the periods of increased and decreased development were short and unsettled, often lasting not more than a few hours, and at most a day or two.

In March, there was scarcely a trace of ozone on the 1st and 2nd, and very little on the 3rd, 8th, 9th, and 16th; considerable quantities on the 13th, 25th, 27th, and 30th, especially on the 25th and 30th. Speaking generally, there was a period of scanty development of ozone till the middle of the month, and then a period of more plentiful development towards the end; but neither of these periods was well defined or settled.

There is an expression in my letter published in the Chemical News of March 1, which requires correcting. For "The period of ozone which commenced on January 20 still continues," read, "Since the period of ozone which commenced on January 20, there has been no decided period of non-ozone."

I am, &c. R. C. C. L.

Seagrove House, Bournemouth, April 9.

The Mnemonic Nomenclature.

To the Editor of the Chemical News.

Sir,—The nomenclature for which you give credit to Mr. Tillman, of New York, in the Chemical News of March 1, in fact belongs to a former generation. It had its birth in 1820-30. It was first published, fully elaborated, in Gmelin's "Handbuch," 1827. Shortly afterwards it was introduced to the English public, but modified for the sake of euphony, by John J. Griffin in his "Chemical Recreations" (first edition), pp. 67-184, and again (1834) in his little book on chemistry, pp. 245-276. It is a singular fact that Mr. Tillman appears to be the only one who lays claim to its invention. Griffin acknowledges indebtedness to Gmelin, Gmelin to Laurent, Laurent to Dumas. The precise relation of these gentlemen is as follows:—Dumas suggested that the vowels be made to indicate the number of equivalents of chlorine in compounds containing that element. Laurent suggested that such use of the vowels be extended to all the elements. Gmelin embodies these ideas in practice in a way to best accommodate itself to the German language. Griffin translates into English, and modifies the system so as more nearly to adapt it for common use. Those who are curious on the subject may consult the references above given, and Gmelin's "Handbuch" (Cavendish Society ed.), vol. vii. pp. 149-153, and Laurent's "Méthode," pp. 47-48, Paris, 1854. I am, &c.

Charles A. Seely.

New York, March 23.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Coriamyrtin (C = 12, O = 16).—J. Riban. The expressed juice of the shoots of *Coriaria myrtifolia*, the poisonous myrtle-leaved sumach, after treatment with plumbic subacetate and filtration, yields coriamyrtin to ether. 1200 kilos. of young shoots gave 87 grammes of pure substance. Coriamyrtin, $C_{29}H_{36}O_{10}$, or $C_{30}H_{36}O_{10}$, is solid, white, very poisonous, crystallising in oblique rhombic prisms, melting at 220°, slightly soluble in water, very soluble in boiling alcohol or in ether, turning the plane of polarisation to the right, neutral, not combining with acids nor with platinic chloride, containing H_2 replaceable by bromine or chlorine, $C_{30}H_{34}Br_2O_{10}$ described. Boiled with baric hydrate and water, it assimilates $5H_2O$, producing an acid. It reacts in the same way with calcic or plumbic oxide and water. The salts so formed are hygroscopic, and give up their acid if treated with sulphuric or oxalic acid. The acid when free is soluble in water, amorphous, and expels carbonic anhydride. Treated with nitric acid, coriamyrtin gives rise to small quantities of a nitro compound not analysed. With acetic anhydride it forms $C_3H_{30}(C_2H_3O)6O_{10},3H_2O$, solid, colourless, brittle, bitter, melting below 100°, insoluble in water, soluble in alcohol. A trace of coriamyrtin moistened with iodhydric acid conc., evaporated on water-bath, and taken up with alcoholic soda solution, gives an intense purple-red solution, decomposed by water.—(*Bull. Soc. Chim. Paris*, 1867, 79.)

Gaseous Volcanic Products at Santorin.—Fouqué. Observations formerly made at Vesuvius and Etna, and confirmed at Santorin, show that the quantity of hydrogen varies directly with the intensity of volcanic activity. At Santorin the proportion of hydrogen varied inversely, that of marsh-gas and carbonic anhydride varied directly, with the distance from the centre of volcanic force, or with the time elapsed from the commencement of the eruption. The quantity of sulphydric acid varies directly as the temperature. More chlorhydric acid is given off than sulphydric or sulphurous acid.—(*Comptes R.* lxiv. 189.)

Oxygen, Preparation of.—A. Mallet. An appropriate vessel containing moist cuprous chloride mixed with sand or kaolin, and traversed by a current of air, is caused to rotate; when the cuprous salt is converted into oxychloride, the temperature is raised to about 400°; rotation being continued, oxygen is then given off. The operation is continuous, and may be repeated any number of times without loss. If chlorhydric acid be employed instead of air, cupric chloride is produced from whic chlorine may be expelled.—(*Comptes R.* lxiv. 226.)

Glass.—Bontemps thinks that the easy devitrification of Pelouze's glass (Chemical News, xv. 160) is due, not to its high percentage of silica, but to the lime in it. Gaudin, indeed, has made microscope lenses of quartz fused by the oxyhydrogen blowpipe. He thinks that the yellow colour attributed by Pelouze to ferric oxide and alkaline sulphides may be due to manganese, and quotes his own experience in support; and further remarks that in his experience manganiferous soda glass turned yellow, or, if containing potash instead of soda, it turned violet.—(*Comptes R.* lxiv. 228.)

Alcohols (C = 12, O = 16).—E. Erlenmeyer. The common view of the normal alcohol series is that its members differ by increments of CH_2. Erlenmeyer finds that normal butylic alcohol is methylic alcohol in the Me of which H_1 is replaced by pseudopropyl; normal amylic alcohol is ethylic alcohol in the Me of which H_1 is replaced by pseudopropyl. Wurtz's amylenic hydrate is pseudopropylic alcohol in which Me_1 is replaced by pseudopropyl; in other words, it is ethylic alcohol in the methylene of

which H_1 is replaced by pseudopropyl. The experimental evidence will be presently brought forward.—(*Zeitschr. Chem., N. F.*, iii. 117.)

Vapour-density of Nitric Peroxide (O = 8).—H. Ste.-Claire Deville and L. Troost. Determinations at intervals of about 10° between 26·7° and 183·2° show that between 26·7° and 100° the vapour-density of this body varies between 2·65 and 1·68, between 100° and 183° it varies between 1·68 and 1·57, an amount within experimental error, and therefore negligeable: the number 1·57 corresponds closely enough to the theoretical number 1·589, NO_4, 4 volumes. If, in accordance with the views of some chemists, the formula be doubled, and written N_2O_8, then the equivalent volumes must be 8. Wurtz admits that NO_4, 2 volumes, dissociates at the moment when experiment gives 4 vapour volumes; but oxygen, meeting its equivalent quantity of nitric oxide, indicates a temperature of 98·5°, at which temperature the experimental number is 1·68, close upon the theoretical number 1·59, corresponding to 4 volumes; dissociation is, therefore, out of court. In the case of vapours condensable above 0°, what is called vapour-density is a mathematical fiction, without meaning in a physical sense: its interpretation is only possible when the vapour, at a point sufficiently above the boiling-point, obeys Mariotte's law, and possesses the constant coefficient of expansion of true gases, ·00367; then the density, reduced to 0° and 760 millimetres, is exactly that of a vapour at these points if it lost the property of condensation.—(*Comptes R.* lxiv. 237.)

Aniline Colours from Protein Compounds.—Dr. O. E. Erdmann. In August, 1866, Erdmann observed that some roast veal was superficially red; he succeeded in transferring some of the red matter to many substances, on which, favoured by moisture and an appropriate temperature, the red matter grew apace. The chemical relations of the colouring matter resemble those of triphenylrosaniline. The microscope showed that only the protein compounds were red, and that the accompanying clouds of infusoria were colourless; indeed, the study of cases of inoculation showed that multitudes of infusoria swarmed about the spot inoculated before any colour appeared; only after the red colour had spread over large surfaces did any mould appear, and this, when it appeared, arrested the progress of the infusoria. The colouring matter is probably produced by the infusoria in the same sense as alcohol, glycerin, &c., are produced by yeast. Researches of Haubener, Fuchs, Ehrenberg, and others on blue milk gave results closely analogous to those here described. An historical review of instances of "the bleeding Host," &c., commencing with the siege of Tyre by Alexander, 332 B.C., on which occasion a soldier's loaf suffered from hæmorrhage, is included in this paper.—(*Journ. prakt. Chem.* xcix. 385.)

Manganese, Cyanogen Compounds of (Mn = 55·14.)—R. Fittig. Manganic cyanide, dissolved in potassic cyanide solution diluted with alcohol, gives, on standing, a precipitate of small blue plates, decomposed by water, but crystallising from potassic cyanide solution in splendid dark blue transparent square tables, which should be quickly removed from the mother liquor, as they are very unstable. Their formula is $MnCy_2+4KCy$. Unalterable at 100°, they change at 200° to a brown substance. If alcohol be added to a solution of manganic cyanide in potassic cyanide which has been kept several days, or which has been boiled, a red precipitate is obtained identical with Rammelsberg's salt. The baric salt, corresponding to the first-mentioned potassic salt, separates in blue crystalline groups from a solution of manganic acetate mixed with excess of baric cyanide. It is insoluble in cold, and decomposed by boiling water.—(*Zeitschr. Chem.*, N. F., iii. 107.)

Bromtoluol, Action of Sodium on (C = 12).—R. Fittig. In this reaction, ditolyl is produced (*Zeitschr. Chem.*, N. F., ii. 312); also a small quantity of crystallisable hydrocarbon, supposed to be dibenzyl, but now found to be identical with Laurent's stilbene, called by Märcker and Limpricht toluylene. It crystallises in the form so characteristic of stilbene, melts at 119·5°, and has the formula $C_{14}H_{12}$. It probably arises from a secondary action, $4C_7H_7Br+4Na = C_{14}H_{12}+2C_7H_8$. Ditolyl seems to be identical with the hydrocarbon obtained by Limpricht by heating chlorbenzyl and water (*Zeitschr. Chem.*, N. F., ii. 280), in which reaction it appears that the chlorine of $C_6H_5(CH_2Cl)$ carries with it H_1 from the benzol residue, and the remaining $C_6H_4(CH_2)$ condenses and splits into anthracene and ditolyl.—(*Zeitschr. Chem.*, N. F., iii. 118.)

Mesitylene, Derivatives of (C = 12, O = 16).—R. Fittig. Monobrommesitylene, from direct action of bromine on mesitylene, is colourless, and boils without decomposition at 225°, sp. gr. 1·3191 at 10°; chromic or nitric acid oxidises it to brommesitylenic acid, $C_9H_9BrO_2$, crystallising from alcohol in powerfully refractive prisms, difficultly soluble in water. Dibrommesitylene, easily made from monobrommesitylene or from mesitylene, crystallises from alcohol in colourless needles, melting at 60°, boiling undecomposed at 285°. Tribrommesitylene, described by Hofmann, is more soluble in benzol than in alcohol, crystallises in needles, and melts at 224°. Nitromesitylene occurs in the preparation of mesitylenic acid, or in the action of nitric acid sp. gr. 1·38 on mesitylene; it is crystallisable from alcohol in large prisms, melting at 41°, boiling undecomposed between 235°—240°. Dinitromesitylene results from the action of fuming nitric acid on brommesitylene; almost insoluble in cold alcohol, it crystallises in colourless prisms from hot alcohol, and melts at 189°—190°. Amidomesitylene (mesidine), prepared by the sluggish action of tin and boiling chlorhydric acid on nitromesitylene, and separation by ammonia, is slightly soluble in boiling water, in which it melts to oily drops.—(*Zeitschr. Chem.*, N. F., iii. 102.)

Camphor, Action of Zincic Chloride on (C = 12).—R. Fittig. The reaction is not so simple as might be expected from Gerhardt's statement that a hydrocarbon of the composition of cymol is produced. After almost innumerable fractionations toluol and xylol were identified in the portion boiling below 150°; from the fraction boiling at 164°—167° tribrom- and trinitro-cumol were prepared identical with the corresponding derivatives of cumol from coal tar; the fraction between 173°—176° consists chiefly of a hydrocarbon probably identical with cymol from oil of cumin; from it a small quantity of tribromcumol identical with that before described, and a large quantity of a heavy oily brominetted body, were obtained; with chromic acid terephthalic and acetic acids were obtained. Between 185°—188° a hydrocarbon $C_{11}H_{16}$ homologous with benzol was obtained, boiling ultimately at 186°—187°, sp. gr. 887 at 10°, giving with bromine a body crystallising from alcohol in fine needles, probably $C_{11}H_{13}Br_3$, melting a little above 100°, and with nitric and sulphuric acids mixed a crystallisable trinitro compound, melting at 84°, soluble in hot alcohol; dilute nitric acid oxidised this hydrocarbon to an acid volatile in steam and forming an easily soluble baric salt which is crystallisable. Further reasearches on this acid are progressing.—(*Zeitschr. Chem.*, N. F., iii. 104.)

MISCELLANEOUS.

The Royal Society.—On Saturday evening, April 13, the President of the Royal Society held the second of his annual *soirées* at Burlington House. The attendance was not so numerous as on the former occasion, owing to the great number of scientific men who are now resident in Paris. Among things interesting to chemists we noticed a new form of ozone generator for decolorising sugar and other substances, exhibited by Mr. Edward Beanes,

F.C.S.; the aëlloscope, or storm-indicator, exhibited by the inventor, Mr. H. A. Clum; various forms of Dr. Richardson's apparatus for producing local anæsthesia, by Messrs. Krohne and Sesemann; a new self-registering railway-signal light, by Mr. W. W. Preece. Mr. H. C. Sorby, F.R.S., exhibited spectrum microscopes, with new improvements, and application in new directions; also, a direct vision hand spectrum telescope. Mr. J. Browning exhibited a silvered glass speculum 13 inches in diameter, micro-spectroscopes and illustrations, and 15 drawings of Mars taken during the recent apposition by the exhibitor. Messrs. Powell and Lealand exhibited patent binocular microscopes. A new form of air-pump for obtaining the most perfect exhaustion by mechanical means, by Mr. J. Barrett, was exhibited by Mr. Ladd. Mr. Ladd also exhibited a form of magneto-electric machine for the conversion of dynamic into electric force which he has lately invented. Dr. Gladstone exhibited absorption spectra as shown by liquids contained in hollow wedges. Professor Tennant exhibited specimens of precious stones and Derbyshire inlaying. Messrs. Troughton and Simms exhibited a spectroscope designed by Mr. W. Huggins, F.R.S.; a double image micrometer; and a 3-feet theodolite, the principal parts being made of aluminium bronze. Messrs. Cooke and Sons exhibited a portable and universal equatorial with telescope of 4-inch aperture, and a 12-inch transit circle with telescope of 2-inch aperture, arranged for use also in the prime vertical. Mr. Pulvermacher exhibited new batteries described as new volta-electric imperishable chain batteries, restorable in magnesium and zinc. Mr. E. J. Reed, of the Admiralty, exhibited models of iron ships, among them a rigged model of the Prussian iron-clad frigate *Wilhelm I.*, the most powerful ship yet laid down in any country. A vacuum tube (curious as a specimen of glass-blowing) for illustration of the electric discharge *in vacuo* was exhibited by Mr. E. Atkinson. Our readers will perceive that the list of objects exhibited included many novelties possessing great interest.

Sulphate of Manganese.—Wishing to make some of this salt, I adopted the following formula, which gives an abundant yield of the pure salt:—Introduce into an iron crucible a mixture of five parts of peroxide of manganese and three-fourth parts of coarsely powdered charcoal. Cover the crucible, and heat to redness until all the charcoal is consumed. Allow the contents of the crucible to cool, place in a porcelain dish, and add 6½ parts of sulphuric acid. Evaporate nearly to dryness, return the mass to the crucible, and heat to redness. When cool rub to powder, if necessary, and treat twice successively with eight parts of boiling water; mix the liquors, filter and evaporate until a pellicle begins to form, when set aside to crystallise. If evaporated too far an insoluble sulphate is deposited (probably in a peculiar state of hydration); hence care must be taken to remove it from the sand-bath as soon as a pellicle begins to form. When a good article of peroxide of manganese is used, this formula will give an abundant yield of perfectly pure sulphate of manganese. Any iron or copper present is destroyed by heating the crude salt to redness.—*C. L. Diehl, Am. Pharm. Assoc.*

Drilling Glass.—A ready and inexpensive mode of drilling glass slides may be of use to some of your numerous readers. Obtain a small three-sided saw file; grind the apex into a triangular sharp point—not too acute, as it will be apt to break if the steel is, as it should be, very hard—apply the sharp point of the file (previously wetted with turpentine) to the glass to be perforated, with firm pressure, keeping the point of the file in the same spot, and giving the upper part a motion from side to side, and also circular. The moment the surface of the glass is abraded the action will go on rapidly, keeping the point still wet with spirit of turpentine. When half way through, it is best to begin on the other side of the glass. When the aperture is made sufficiently large, it may be increased by using a small "rat-tailed" file, kept wet with the turpentine.—*J. B. Spencer, in Hardwicke's "Science Gossip."*

Notes on Testing the Purity of Glycerin.—I should regard a glycerin as unobjectionable for medicinal purposes, if it forms a colourless mixture with twice its volume of strong alcohol and of sulphuric acid; and if, after previous dilution with distilled water, it yields no turbidity, either cold or on heating to the boiling point with sulphuretted hydrogen, ferrocyanide of potassium, nitrate of baryta, oxalate of ammonia, or nitrate of silver. This last test I regard as an important one, since I believe that all those compounds, which impart to common glycerin a peculiar rancid odour, will reduce the silver salt and impart a colour to the liquid on boiling, even though that odour may be scarcely apparent, while pure glycerin is not affected by boiling with nitrate of silver, although, like nearly all organic and many inorganic compounds, it gradually assumes a darker colour on exposure to light.—*J. M. Maisch, in American Journal of Pharmacy.*

As cane-sugar syrup may be used as an adulterant, its presence may most satisfactorily be detected by diluting a little of the suspected glycerin with three parts of water, adding a few grains of tartaric acid, and boiling a few moments. Then add the solution of sulphate of copper, followed by the potassa, when the reddish suboxide will at once appear, if cane sugar had been present, the tartaric acid having changed the cane sugar into glucose.—*W. Proctor, in American Journal of Pharmacy.*

ANSWERS TO CORRESPONDENTS.

*** In publishing letters from our Correspondents we do not thereby adopt the views of the writers. Our intention to give both sides of a question will frequently oblige us to publish opinions with which we do not agree.

Vol. XIV. of the Chemical News, containing a copious Index, is now ready, price 11s. 0d., by post, 11s. 6d., handsomely bound in cloth, gold-lettered. The cases for binding may be obtained at our Office, price 1s. 6d. Subscribers may have their copies bound for 2s. 6d. if sent to our Office, or, if accompanied by a cloth case, for 1s. Vols. I., II., and VII. are out of print. All the others are kept in stock. Vol. XV. commenced January 4, and will be complete in 26 numbers.

J. W. Swindells.—Received with thanks.

A Chemical Novice.—The article on "Sulphate of Magnesia" in last week's Chemical News will doubtless afford all the information required.

D. Waldie, Calcutta.—The letter and book packet have arrived safely. The report on the water supply is of considerable value, and we will take an early opportunity of returning to the subject.

Torelli's Ice Machine.—*T. P. Hawksley.*—We are not aware that the machine can be obtained in this country. Apply to the makers in Paris.

Cement.—In the receipt for alum and plaster cement, given a few numbers ago, it should have been mentioned that the alum should be melted over a fire, and the plaster of Paris then added in sufficient quantity to form a paste.

Red Liquor.—*J. W.*—In reply to a question on this subject in last week's Chemical News, a correspondent has kindly informed us that the colouring matter of commercial red liquor (acetate of alumina) is generally peach or brazil wood.

Acetonitrate of Bismuth.—J. Wallace wishes to know how to make the above so as not to precipitate on the addition of water. We are not aware that acetic acid will prevent the precipitation of bismuth salts on addition of water. Citric acid is generally used for that purpose.

Jesse Fisher.—The sample of tetrachloride of carbon arrived safely. It appears to be almost chemically pure. At present the demand for the article is limited; its commercial uses have to be found out. Probably in this, as in many other instances, the supply will create a demand.

A Chemical Novice.—1. Add chloride of ammonium to the impure sulphate of magnesia, then ammonia, and boil; the iron will be precipitated in the state of sesquioxide. If you want to ascertain the exact quantity present, this precipitate can be collected on a filter, ignited with the usual precautions, and weighed.—2. Perhaps the best plan for ascertaining the value of magnesian limestone would be to find out how much sulphate of magnesia you could make from a certain weight, say 7 lbs.—3. If you find the presence of iron interfere with the product, you may, perhaps, prevent the sulphate of iron crystallising with the sulphate of magnesia by peroxidising the iron with nitric acid. This will convert the iron into a persulphate which is not readily crystallisable.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On the Stability of Gun-cotton, by* F. A. Abel, *F.R.S., V.P.C.S.*

It has been shown in the memoir "*On the Manufacture and Composition of Gun-cotton*," published last year,† that modifications in the processes of conversion and purification, which appear at first sight of very trifling nature, exert most important influences upon the composition and purity of the product.

Very numerous and extensive experiments and observations have been carried on during the last four years at Woolwich, both with small and large quantities of gun-cotton, for the purpose of completely investigating the conditions by which the stability of this substance, when under the influence of light and heat, may be modified, and with a view to ascertain whether results recently arrived at in France apply to gun-cotton as manufactured in this country.

The principal points which have been established by the results arrived at in these investigations may be summed up as follows:—

1. Gun-cotton produced from properly purified cotton, according to the directions given by Von Lenk, may be exposed to diffused daylight either in open air or in closed vessels for very long periods without undergoing any change. The preservation of the material for three and a half years under those conditions has been perfect.

2. Long-continued exposure of the substance in a condition of ordinary dryness to strong daylight and sunlight, produces a very gradual change in gun-cotton of the description defined above; and the statements which have been published regarding the very rapid decomposition of gun-cotton when exposed to sunlight do, therefore, not apply to the nearly pure trinitrocellulose obtained by strictly following the system of manufacture now adopted.

3. If gun-cotton in closed vessels is left for protracted periods exposed to strong daylight or sunlight in a moist or damp condition, it is affected to a somewhat greater extent; but even under these circumstances the change produced in the gun-cotton by several months' exposure is of a very trifling nature.

4. Gun-cotton which is exposed to sunlight until a faint acid reaction has become developed, and is then immediately afterwards packed into boxes which are tightly closed, does not undergo any change during subsequent storage for long periods. (The present experience on this head extends over three and a half years.)

5. Gun-cotton prepared and purified according to the prescribed system, and stored in the ordinary dry condition, does not furnish any indication of alteration beyond the development, shortly after it is first packed, of a slight peculiar odour, and the power of gradually imparting to litmus, when packed with it, a pink tinge.

6. The influence exercised upon the stability of gun-cotton of average quality, as obtained by strict adherence to Von Lenk's system of manufacture, by prolonged exposure to temperatures considerably exceeding those which are experienced in tropical climates, is very trifling in comparison with the results recently published by Continental experimenters relating to the effects of heat upon gun-cotton, and it may be so perfectly counteracted by very simple means, which in no way interfere with the essential qualities of the material, that the storage and transport of gun-cotton presents no greater danger, and is, under some circumstances, attended with much less risk of accident than is the case with gunpowder.

7. Perfectly pure gun-cotton, or trinitrocellulose, resists to a remarkable extent the destructive effects of prolonged exposure to temperatures even approaching 100° C., and the lower nitro-products of cellulose (soluble gun-cotton) are at any rate not more prone to alteration when pure. The incomplete conversion of cotton into the most explosive products does, therefore, not of necessity result in the production of a less perfectly permanent compound than that obtained by the most perfect action of the acid mixture.

8. But all ordinary products of manufacture contain small proportions of organic (nitrogenised) impurities of comparatively unstable properties, which have been formed by the action of nitric acid upon foreign matters retained by the cotton fibre, and which are not completely separated by the ordinary or even a more searching process of purification.

It is the presence of this class of impurity in gun-cotton which first gives rise to the development of free acid when the substance is exposed to the action of heat; and it is the acid thus generated which eventually exerts a destructive action upon the cellulose products, and thus establishes decomposition, which heat materially accelerates. If this small quantity of acid developed from the impurity in question be neutralised as it becomes nascent no injurious action upon the gun-cotton results, and a great promoting cause of the decomposition of gun-cotton by heat is removed. This result is readily obtained by uniformly distributing through gun-cotton a small proportion of a carbonate; the sodic carbonate, applied in the form of solution, being best adapted to this purpose.‡

9. The introduction into the finished gun-cotton of 1 per cent. of sodic carbonate affords to the material the power of resisting any serious change, even when exposed to such elevated temperatures as would induce some decomposition in the perfectly pure cellulose products. That proportion affords, therefore, security to gun-cotton against any destructive effects of the highest temperatures to which it is likely to be exposed even under very exceptional climatic conditions. The only influences which the addition of that amount of carbonate to gun-cotton might exert upon its properties as an explosive would consist in a trifling addition to the small amount of smoke attending its combustion, and in a slight retardation of its explosion, neither of which could be regarded as results detrimental to the probable value of the material.

10. Water acts as a most perfect protection to gun-cotton (except when it is exposed for long periods to sunlight), even under extremely severe conditions of exposure to heat. An atmosphere saturated with aqueous vapour suffices to protect it from change at elevated temperatures, and wet or damp gun-cotton may be exposed for long periods in confined spaces to 100° C. without sustaining any change.

Actual immersion in water is not necessary for the

* Abstract of a paper read before the Royal Society, April 4, 1867.

† *Trans. Royal Society.*

‡ The deposition of calcic and magnesian carbonates upon the fibre of gun-cotton, either by its long-continued immersion in flowing spring water or by its subjection to the so-called "silicating" process adopted by Von Lenk, exerts a similar protective effect, which, however, is necessarily very variable in its extent, as the amount of carbonate thus introduced into a mass of gun-cotton is uncertain; moreover, as it is only loosely deposited between the fibre, the proportion is liable to be diminished by any manipulation to which the gun-cotton may be subject.

most perfect preservation of gun-cotton; the material, if only damp to the touch, sustains not the smallest change, even if closely packed in large quantities. The organic impurities, which doubtless give rise to the very slight development of acid observed when gun-cotton is closely packed in the dry condition, appear equally protected by the water; for damp or wet gun-cotton, which has been preserved for three years, has not exhibited the faintest acidity. If as much water as possible be expelled from wet gun-cotton by the centrifugal extractor, it is obtained in a condition in which, though only damp to the touch, it is perfectly non-explosive; the water thus left in the material is sufficient to act as a perfect protection, and consequently also to guard against all risk of accident. It is therefore in this condition that all reserved stores of the substance should be preserved, or that it should be transported in large quantities to very distant places. If the proper proportion of sodic carbonate be dissolved in the water with which the gun-cotton is originally saturated for the purpose of obtaining it in this non-explosive form, the material, whenever it is dried for conversion into cartridges or employment in other ways, will contain the alkaline matter required for its safe storage and use in the dry condition in all climates.

On the Action of Permanganate of Potassium on certain Metals, by W. B. GILES.*

THE powerful action which a cold saturated solution of permanganate of potassium exerts upon metallic mercury has not been previously noticed, as far as I am aware; a short account of this reaction may, therefore, be acceptable.

On examining the action of this salt on some other metals, I was surprised to find that zinc, which oxidises so readily under ordinary circumstances, is apparently not in the least degree attacked by the solution—in fact, rods of the pure metal may be kept in a bottle with the solution for two months without any perceptible change occurring. Mercury, however, which is generally classed with gold and silver as a metal somewhat difficult to oxidise, is most readily and completely converted into mercurous oxide in a short time. An ounce or so of mercury may be enclosed in a stoppered bottle with a solution of permanganate saturated at the ordinary temperature. If the bottle is violently shaken, the metal will immediately become disintegrated, and will appear as a powder, each minute globule of metal being coated with a film of oxide, which prevents its reunion with the rest. If the bottle be incessantly shaken, the solution will be deprived of all colour in a short time; but even if the bottle be left at rest, and only an occasional shake be given, the change will be complete in about twenty-four hours. The action is, of course, much retarded by the clogging nature of the manganic oxide on the metal. The colourless fluid, when all the action is over, is strongly alkaline, and contains free hydrate of potassium; and if the permanganate be renewed as often as it is decolorised, there is no difficulty in oxidising the whole of the mercury. The ensuing dark-brown powder is easily resolved by elutriation into brown manganic oxide and black mercurous oxide, in consequence of the great difference in their specific gravity. The oxide so obtained is in all respects similar to that obtained by the ordinary methods. A curious intermediate stage of the oxidation is noticed towards the end of the experiment. The permanganate is not directly deoxidised, but first passes to manganate—the colour, of course, changing from purple to bright green. The action is much more rapid if the mercury and the permanganate are boiled together; in this case, however, a certain amount of mercuric oxide appears to be formed, and the change to manganate is not observed.

This salt also appears to exert a slight action on pure silver, but the few trials I have made have given me rather anomalous results, some pieces of silver being apparently superficially oxidised, whilst others were not acted upon.

The solution has no action upon copper, not even when kept at 100° C. for several hours. It would be interesting to know if this salt has any action on magnesium and thallium, both being metals prone to oxidation.

40, Highfield Street, Liverpool.

[Neither aluminium nor magnesium exerts any apparent action on dilute permanganate of potassium in the cold. After long ebullition a deposit of brown oxide of manganese is formed, but the solution is not decolorised unless excessively weak. Thallium exerts a more powerful action, and, even in the cold, gradually decomposes the permanganate.—ED. *C. N.*]

On the Preparation of Pure Distilled Water, by J. STAS.

IN my "*Recherches sur les Rapports Réciproques des Poids Atomiques*,"* I showed the means I employed to procure pure distilled water for my experiments. The best method of destroying volatile organic matter liable to become fixed either spontaneously or under the influence of the mineral acids, is, as I stated, to pass the vapour of water slowly through a long tube of red-hot copper bent in a zigzag form, filled with roasted copper turnings, and heated to bright redness in a furnace, and to distil a second time the water condensed from this vapour, using a platinum refrigerator. This method, which is perfect as far as regards the quality of the product, is not quite satisfactory when large quantities of pure water are wanted, as was the case for my present researches. In fact, the passage of the vapour through the red-hot copper tube causes a sufficient lowering of the temperature to prevent the oxide of copper acting upon the organic matter, if the current of vapour is a little too rapid. It is necessary, therefore, to distil very slowly. This inconvenience determined me to find a quicker method. This I succeeded in doing by using a mixture of manganate and permanganate of potassium to destroy the organic matter. The following is the way in which I obtained, by this method, the very considerable quantities of pure water that I required for my researches. I prepared manganate of potassium by the action of hydrate and chlorate of potassium on binoxide of manganese. The pulverised product was mixed with the smallest quantity of water necessary to dissolve the whole of the manganate formed, and the mixture left at rest in a closed vessel. Four or five per cent. of the solution, which had become clear and of a deep green colour, was added to the water to be distilled, and the mixture left to react for four-and-twenty hours. I also put in the retort a litre or two of a concentrated solution of manganate of potassium, with an equal volume of a solution of hydrate of

* Communicated by the author.

* See CHEMICAL NEWS, iv. 207.

potassium sufficiently concentrated to give stability to the salt and to enable its dilute solution to resist for a longer time the action of the heat without decomposing. I then filled the retort about eight-tenths full of the water which had been acted upon by the manganate of potassium, and proceeded to distil it in the usual way.

When it boiled the fire was slackened to avoid carrying over the liquid, which, for some moments, produces a somewhat abundant frothing. When this is over the water may be boiled freely without any inconvenience. After about the first twentieth of the water has passed over as vapour, the latter is quite free from organic matter, and even from inorganic matter, if the tube is furnished with diaphragms for arresting the small drops of liquid always carried over by brisk boiling. In this way a person used to such distillation may produce *at once* water in which it is impossible to discover the slightest trace of organic matter or of the fixed matter existing in the retort. Nevertheless, when I required water quite free from matter, either fixed or capable of becoming so, I took care to submit the water to a fresh distillation, taking the precaution of using as refrigerator a long platinum tube soldered with gold; generally, also, the water, as it was condensed, was used in the washing for which it was required.

I should add that, having sometimes used *rain* instead of spring water to procure pure distilled water from, by means of manganate of potassium, I found sensible quantities of ammonia in the condensed water, which proves that the manganate does not destroy that base. It is, then, indispensable to submit the water to a fresh distillation, with some thousandths of monosodic or monopotassic sulphate.

I will not here refer to the properties which pure water ought to have, nor to the means of ascertaining its purity. I have entered sufficiently upon these subjects in the work mentioned at the beginning of this article, to which I refer those who may wish for more details on this subject.

PHARMACY, TOXICOLOGY, &c.

The New Pharmacopœia (1867).

[FOURTH NOTICE.]

Carbolic acid has a complete set of tests supplied for its identification, and as no process is given for making it, we presume that the purest commercial acid is considered trustworthy. Sulphate of atropia, with an officinal solution, is a great acquisition to the list of the mydriatic remedies, so called from their pupil-dilating powers. The value of these topical agents is so undeniable and demonstrated so readily, that a perfect series of them is greatly to be desired, and the history of them is very instructive. Thus, it was found that belladonna caused the pupil to dilate, while contraction was induced by opium—a topical effect indicative of a general special nervous influence. The problem was to separate these, and, by the next step in the discovery, the alkaloids of the respective drugs were tried. Atropia acted topically as a mydriatic, but morphia did not possess a similarly local myosotic power. This was the stage reached by the last British Pharmacopœia; two steps further have been now taken. Atropia is replaced by the less irritating sulphate, and so that series is quite complete; the converse series is continued, but not concluded, for Calabar bean is now officinal, which has a local pupil-contracting power without producing constitutional effects (as does morphia), and so is the converse of atropia. We should have been glad if the group had been completed by the introduction of physostigmine—the alkaloid itself being slightly, the sulphate, chloride, &c., more readily, soluble in water.

Apart from this, the alkaloid of Calabar bean has had a very searching investigation by foreign physiologists, and English authorities on cerebro-spinal disorders have used it very extensively. Moreover, it has been prepared in a state of purity by many London manufacturing firms, that of Messrs. Hopkins and Williams being, we believe, one of the first. If these additions had been made, we should have had a model group of nervous local agents, each counteracting the other—a group whose powers are more unequivocal than those of any other in pharmacy. For instance, as regards effects—

Mydriatics.		Myosotics.	
Constitutional.	*Local.*	*Constitutional.*	*Local.*
Belladonna.	Belladonna.	Opium. Physostigma.	Physostigma.
Atropia.	Atropia.	Physostigmine. Morphia.	Physostigmine.
Sulphate of atropia.	Sulphate of atropia.	Acetate of morphia.	Sulph. of physostigmine.

The bismuth additions are two in number, and we are glad of it, for being a dyspeptic remedy, like iron, we cannot have too many preparations of it, some of such compounds being more easily taken in some conditions, and *vice versâ*.

Iodide of cadmium was first recommended by Dr. Garrod to replace iodide of lead in ointment, a favourite remedy of some, on the grounds that the former, unlike the latter, does not stain the skin yellow, and never induces any constitutional symptoms with the same therapeutic effect. The Pharmacopœia Committee, being above prejudice, give both ointments.

Oxalate of cerium has been found specially useful by some in cases of obstinate vomiting, but this special effect has been quite as frequently denied.

Citrate of ammonia seems very similar in all respects to the acetate, and is restored from the London Pharmacopœia 1851. Effervescing solution of potash reappears from the Pharmacopœia of 1836; seemingly it has not been much missed for thirty years.

Iodide of sulphur, also, is a revived remedy not used internally. The number of lithia preparations has been increased in spite of their rapid falling out of use, although theoretically they promised so well as solvents for some kinds of calculus.

Thus, then, we have noted very briefly the general features of the new work, alluding chiefly to the novelties. A very great concession is made to the grumblers at the last edition by references to the preparations which were contained in it, taken either from the Dublin, Edinburgh, or London Pharmacopœia, with the name only slightly altered. The names of the first edition of the British Pharmacopœia are in most instances retained, but a note here and there tells us what the former name was, and in what way the strength or ingredients of mixtures, &c., have been altered.

The publication of the volume at one uniform price is positively to be delayed no longer. Many as have been the delays, no one will complain if opportunities have been taken up to the latest moment of making it an authoritative book worthy of the British Medical Council. An advertisement has been inserted in the medical papers of a speedy issue of copies, and before another week has passed the British Pharmacopœia of 1864 will be an authority no more.

The present, then, is a fitting time for a short comparison of the two editions. The Pharmacopœia of 1867 is certainly an honest book. It contains good preparations laboriously selected from many sources—from Continental works of the kind, but mainly from the London, Edinburgh, and Dublin Pharmacopœias, the French Codex slightly, with the edition of 1864 for its basis. It has been spoken of favourably on all hands, and its merits must be considerable if we may judge from the different quarters in which its praises have been proclaimed. All say that it is a cheap, good, and practical book.

But the fact has been forgotten that such a success was only possible after a preparation for it, and the way was cleared by the 1864 edition—crude, and approved of only by its framers. The 1864 edition cost a sum of money altogether out of proportion to its value; it was incomplete, it contained too many novelties. All this may be true, but it is a book that will in future times be pointed to with pride as the first national Pharmacopœia in the English language which established a uniform and satisfactory system of weights and measures, and was, after all, a signal triumph over old prejudices and errors. All will be glad of the new edition, but all should try and do justice to the old, which remains a monument of a critical time in modern medicine.

Solution of Meconate of Morphia, by William Procter, *Jr.*

The following working process for preparing this solution is suggested:—

Take of

Opium in powder (or dry enough to powder) 5 troy-ounces,
Stronger alcohol (95 per cent.) a pint,
Distilled water,
Water,
Acetate of lead,
Water of ammonia, of each a sufficient quantity,
Ingredients for generating sulphuretted hydrogen a sufficient quantity.

Macerate the opium in a pint of water with agitation for three days, strain with expression, and again macerate in successive portions of water, a pint each time, for twenty-four hours, until four pints have been used and the opium sufficiently exhausted. Evaporate the liquors carefully to the measure of a pint, filter and add solution of acetate of lead until it ceases to produce a precipitate. Collect this on a filter, wash it with water thoroughly, suspend it in a pint of warm distilled water, pass a current of sulphuretted hydrogen through the mixture until the lead is entirely precipitated, heat and filter the solution of meconic acid that remains, until deprived of sulphuretted odour. Meanwhile, take the liquid filtered from the lead precipitate (containing the morphia, &c.), together with the washings, evaporate them at a gentle heat to four fluid ounces; drop in sufficient diluted sulphuric acid to precipitate the oxide of lead present, and filter; then mix the filtrate with an equal bulk of alcohol, and carefully add the solution of ammonia, with agitation, until it remains in slight excess, allowing it to rest twenty-four hours that the morphia may separate. Collect the impure morphia on a filter, wash it with a little water, and dissolve it in the hot solution of meconic acid, and filter if necessary, washing the filter with a little distilled water. Finally, add first sufficient distilled water to the filtrate to make it measure three pints, and then the stronger alcohol, and mix them.

Thus made, solution of meconate of morphia has a decided bitter taste, but little odour except from the alcohol present, and a light reddish-brown colour, varying in different specimens, and due to adhering colouring matter, and especially to contact with oxide of iron during preparation in filters or utensils.—*American Journal of Pharmacy.*

Pharmacy of the late American War.

Many are the lessons taught by the late civil war in America, but we think that its magnitude is altogether inappreciable, even by the amount of a national debt incurred in such a short space of time. We propose to take another stand-point for estimating this magnitude, with the assistance of the lately published proceedings of the American Pharmaceutical Association. We must premise that, owing to many pressing reasons, chiefly from the inferiority of the drugs, and the high price charged by the contractors for the army medical service, the Government was induced by the Surgeon-General to form pharmaceutical laboratories at the commencement of the year 1863. Two large laboratories were built, one at Philadelphia, the other near New York, and statistics are given for the information of all who take interest in pharmacy on a large scale.

Before giving a short notice of this laboratory at Philadelphia, we must mention that the quantities given were used by one of the two belligerent parties during about half the time of the war, and issued from one only of the two laboratories.

The quantities of drugs taken and bandages used, therefore, during the whole time of the war would certainly be underrated if those given were multiplied fourfold.

The labour at this Philadelphia laboratory was commenced by a force of three young ladies, we are told, by the manufacture of bedclothes, towels, drawers, and shirts. In a short time the work was increased to such an extent that seventy-two sewing-machines and some 250 "hands" were pressed into service.

It is said that a full detail of the internal arrangements and work done would require too much labour, from the materials for such a report being so scattered, and so they will be for ever lost. We very much regret this, as many more pretending reports issued from America do not possess a tithe of the value that such a valuable chapter of medical history would possess.

Attached to the building were a counting-house, shipping, receiving, and packing departments, a glassware department, another for tin cases and boxes, washhouse, stoppering room, steam boilers and engines, and an analytical room.

For converting the crude drugs into the chemical and pharmaceutical products needed, were provided—1st. A mill-room for pulverising (coarsely or finely) and drying. 2nd. A still-room, for the preparations for which steam could be used. 3rd. A furnace-room. 4th. An ether house. A separate building for the manufacture of chloroform and ether. 5th. A filling department in which female hands only were engaged, and with which the manufacture of isinglass plaster, pills, and bandages was connected.

When the work was commenced, a large stock of substances afterwards provided from the laboratory, already existed; besides, medical purveyors bought much from the market afterwards. So an accurate estimation of what was really consumed cannot be given.

Of course there was much interested opposition to the working of this scheme.

And now "to count our gains," bearing in mind the limitations before given. From March, 1863, to September 30, 1865, were actually isssued from the large Philadelphia Laboratory of Pharmacy, &c., 2,318,928 roller bandages, 34,465 yards of isinglass plaster, "alcohol fortius" 141,436 quarts, precisely 3,175,248 opium pills, and 1,292,232 pills, containing each three grains of sulphate of quinine. 6645 lbs. of opium were used in powder, and a quantity of all the following drugs was issued, in every case exceeding 10,000 lbs. by weight. We arrange them in order of quantities, not to serve as an estimate of what drugs were most frequently used, for such would be very fallacious, as a dose of one compound might be a drachm, of another a few grains; but, with this allowed, a fair notion may be given of the general order in the use of the several drugs.

As might be almost expected from the largeness of the dose and general utility, old-fashioned Epsom salts carries off the palm. The quantity of sulphate of magnesia used was 62,611 lbs.; the next highest number is given for linseedmeal—viz., 55,627 lbs.—followed closely by simple ointment, 50,097 lbs. These numbers are by far the highest; the next to them in order are *sinapis nigræ pulvis*, 31,429 lbs.; *syrupus scillæ*, 29,863 lbs.; solution of chlorinated soda, 26,936 lbs.; chloroform, 25,300 lbs.; spirits of nitrous ether, 21,834 lbs.; and so we might prolong the list to some length.

We may observe, as curiosities of pharmacy, during a severe civil war, the issue of 10,594 lbs. of black pepper, 10,257 lbs. of powdered gum arabic, 14,029 lbs. of copaiba balsam, and 3391 lbs. of sulphur.

Ether in America largely replaces chloroform as an anæsthetical remedy, and so we are not unduly surprised at the amount of 16,308 lbs. prepared.

These figures are rather hard to realise as the requirements of a medical department during time of war, for little more than two years and a half, from one establishment. We can only give the statistics presented to the eminent members of the Pharmaceutical Association of America, which has on its roll many of the leading medical names of the United States. These wholesale results tend to show that at critical times in a nation's history a demand has only to exist for the greatest efforts to be made. After the whole of the expenses were paid, the saving to the Government was found to be $766,019·91.

On the Estimation of Phosphoric Acid in the Presence of Alumina.—M. Knap attempted to estimate phosphoric acid in a mineral rich in alumina, by the process founded on the non-precipitation of alumina and ferric oxide by ammonia in the presence of tartaric acid, and obtained no precipitate with sulphate of magnesia, although the presence of phosphoric acid was shown by molybdic acid. To ascertain the cause of this, the author operated on a liquid containing phosphate of alumina, and on another containing ferric phosphate; to them was added tartaric acid, then ammonia, and afterwards sulphate of magnesia; that containing phosphate of iron, at once gave a precipitate containing ammoniaco-magnesian phosphate, whilst the other remained limpid even after several days' exposure in a warm place. Thus the presence of alumina renders the estimation of phosphoric acid impossible by the process in question, for it retains this acid, even whilst dissolved in an alkaline liquid.—*Zeitschrift für Chemie*, ii. 151.

FOREIGN SCIENCE.

(From our own Correspondent.)

Paris, April 24, 1867.

On the demand presented in the name of the French Society of Photography by MM. Regnault and Peligot, the Commission of Coins and Medals has engraved a commemorative medal of the discoveries of Niépce and Daguerre. One of the dies of these medals is to serve as a type for those given as rewards by the Society; and the latter was disposed to engrave at its expense a special die for the reverse, when one of the members of the Council, M. Hulot, director of the manufactory of postage-stamps at the Mint, proposed to engrave it at his own expense, and to place it at the disposition of the Society. M. Hulot, also, struck with the importance of the labours and discoveries of the competitors for the prize of the Duke de Luynes, given to M. Poitevin, has offered to have struck six great medals, to be given to six of the most worthy rivals of the fortunate winner of the prize of 8000 francs. The new and brilliant industry of postage stamps which he furnishes for the Government have enriched M. Hulot, whose generosity increases with his fortune. It is impossible to make a better use of what he has gained by talent and energy.

M. Dubrunfaut has recently made a very important discovery—the presence in Jerusalem artichokes of a large proportion of cane-sugar. This discovery was made ten years ago, but it required to be confirmed by new experiments, which the illustrious chemist could only make this year. The juice of the tubers dug up in September has a vigorous rotatory left-handed motion. Under the influence of yeast it acquires an incomplete alcoholic fermentation, takes the form of a curded mass, and gives a powdery precipitate of well-characterised inuline; the liquid separated from the precipitate, and treated with alcohol, gives a new precipitate of inuline. The juice of the tubers dug up in March or April has a rotatory motion towards the right, and gives no precipitate of inuline either spontaneously or with alcohol; submitted to fermentation it furnishes by distillation the enormous quantity of 8 or 9 per cent. of concentrated alcohol; and treated with alcohol at 92° to 93° to saturation, it gives two products — 1st, an alcoholic solution; 2nd, a gummy precipitate insoluble in alcohol, but quite soluble in water. This solution is optically neutral, and can undergo an alcoholic transformation without losing its neutrality.

F. Moigno.

Iridium in Canada.—The *Keystone News*, March 1, says:—"Mr. Meves, of Madoc, states that iridium exists along with the other materials with which gold has been found in the Richardson mine. The presence of iridium is not mentioned in the reports of Dr. Hunt and Mr. Michel; but as Mr. Meves has obtained his specimens quite recently, they may have been taken from different parts of the vein or "pocket," as this deposit has been called. Iridium is one of the rare metals, and is of extreme hardness. It was found in Californian gold, and its presence in the gold coined at the United States mint caused the destruction of several valuable dies, and from this led to its detection and removal. The same substance is found in the gold of the Chaudiere, as also platinum, and an alloy of osmium and iridium, named iridosmine. The latter is very hard and durable, and is put to a practical use in pointing gold pens and in jewelling. Platinum, it need scarcely be remarked, is a most valuable metal, and if found in the gold region here, as is quite likely, would constitute of itself a valuable discovery. We mention this to encourage explorers to have their eyes open to other things besides gold. Such a tract of country might also be expected to supply precious stones, as chalcedony, amethysts, and other varieties of coloured quartz, jaspers, and even diamonds."

PARIS EXHIBITION OF 1867.

(From our Special Correspondent.)

M. Richter, of Friburg, exhibits two ingots of perfectly pure indium. This metal, the last of those discovered, is rare enough to cost 36 fr. the gramme. The two bars weigh about 500 grammes, and therefore represent a sum of 18,000 fr. There is a great resemblance between indium and cadmium, especially in their chemical nature; also it is difficult to distinguish or separate one from the other. The only tangible difference is that the oxide of indium is insoluble in ammonia. Indium is as white as tin or cadmium; it is volatile, and has a peculiar odour; its spectrum is remarkable for its bright indigo line—hence its name. The indium of the Paris Exhibition of 1867 is the king of chemical products, as thallium was in 1862. But M. Richter has no rival claimant for the honour of the discovery of indium, and is to have a gold medal.

Near this case M. Vée exhibits some products altogether new—viz., eserine, and the preparations of the calabar bean. Eserine, the principal active matter of this bean, first eliminated by the above-named gentleman, is a crystallisable alkaloid, different from the *physostygmine* discovered by M. Jobst and Hesse of Stuttgard. A hundredth part of a centigramme introduced under the eyelids is sufficient to produce a sensible action. M. Vée delivers to the commercial world discs of gelatine containing the twenty-fifth of a milligramme of eserine, granules of eserine for internal use, a glycerate of sulphate of eserine for collyria, discs of gelatine containing the twenty-fifth part of a milligramme of sulphate of atropine, in order to produce the dilatation of the pupil—an effect opposite to that of discs of eserine. His calcined magnesia, and preparations of magnesia, hydrated magnesia, heavy calcined magnesia (produced by burning the hydrate), magnesium mixture (a fluid preparation containing a tenth of its weight of hydrated magnesia), his effervescing magnesia lemonade, have been well developed in France, Austria, and England.

M. François Cerio, owner of the gastronomic establishment at Turin, exhibits a method of preserving meat, flesh of all sorts, vegetables and fruits, and in general all substances usually treated by salt or saltpetre. This is so simple and efficacious that we are astonished it was not discovered and put in practice earlier. The machine consists of a receiver, able to preserve a vacuum when closed by a cover also impenetrable to the air. It is furnished at the top with two pipes, with stop-cocks communicating one with the exhausting machine, the other with a vessel containing a solution of common salt (with the addition of 2 to 5 per cent. of nitrate of potash or saltpetre, if the meat is required to take a high colour). The cover being removed, the substance to be preserved is inserted; the vessel is then closed tightly, and the cock communicating with the exhauster is opened, and the vacuum is made, if possible, down to five millimetres' pressure. The exhausting cock is then shut, and the brine cock is opened; the salt liquor is allowed to remain in contact with the substance to be preserved for a certain time, depending upon its mass, which never exceeds a few minutes. The substance is then removed and hung up to drain in a well-aired place; after a few days it is dry, and fit for putting in a case for sending off to any distance.

Let me remark that, in proportion as the expansion proceeds, the food to be preserved swells up and increases in volume one-third more than its original bulk. It is on account of this considerable opening of the pores or void spaces that the alimentary substance placed in contact with the saline liquors absorbs the necessary quantity for its preservation, if not indefinitely, at least long enough to warrant its expedition for a long voyage.

Thus treated, the substance preserved loses absolutely none of its nutritive elements—fibrin, albumen, creatin, &c. It loses its colour by drying, but the interior preserves the fresh tint, odour, and taste peculiar to it. When cooked, it retains very slight traces of salt. I can affirm that, by this mode of preparation, the substances prepared keep all their natural properties and qualities, and are able to replace, without inconvenience, fresh food.

It may certainly happen that, after having remained for some time packed in a case, they may acquire somewhat of an odour; yet this is only superficial, which goes off by exposure to air, and disappears entirely by being steeped for a few hours in water. I have seen a carp weighing 5 to 7 kilogrammes that M. Cerio brought from Turin, and which was exhibited, among other specimens, at the Society of Encouragement at the last sitting. This invention presents the following advantages:—

1. Immense saving of time, since it requires only a few minutes for complete preservation, instead of several days, and sometimes months.

2. The possibility of operating at all times, no matter under what atmospheric circumstances, while the ordinary salting methods are injuriously affected by certain states of pressure and humidity of the air.

3. Economy of salt and saltpetre in the very great proportion of 80 per cent.

4. Imperceptible waste of the substance; whilst under ordinary processes the preserved food loses a considerable proportion of nutritive element.

5. Absolutely certain success, whilst the old processes give imperfect results.

6. Preserving food in a degree superior in quality and soundness.

The machines or apparatus of exhaustion, furnished with a free piston in the same manner as the air-pumps of M. Deleuil, seem to have been specially invented for the purpose of rendering possible the practice on a large scale of the process of M. Cerio. The inventor declares that he is able to deliver any quantity of meat that can be henceforth required for either the armies or navies of France or England, and that he will prepare it at the markets of Italy or France, or at the immensely abundant markets of Paraguay, the Pampas, Texas, &c., where meat costs almost nothing. His discovery is certainly one of the most important of the Exhibition of 1867, and I can warmly applaud it.

In Group VI., Classes 45, 21, is exhibited the apparatus for the manufacture of sugar by osmose. This apparatus is called the osmogene. In the *Mondes* of August 11, 1864, were described some experiments in the factory of Courrières, near Valenciennes, of an osmogene apparatus that M. Dubrunfaut, the celebrated French manufacturing chemist, had patented in June, 1863, with a view of removing, by endosomose or osmose, from molasses or juice, the salts which they contain, and which prevented the crystallisation of the sugar.

Now facts have brought to light the real state of the process, MM. Camichel and Co., sugar manufacturers and distillers, at La Tour-du-Pin, exhibit the results obtained during the seasons 1864, 1865, and 1866.

Each osmogenic apparatus requires a space of 1 m. 35 c. height, 1 m. 12 c. long, and 1 m. 32 c. wide, besides the height required for the distributing vessels for water and molasses. It includes 50 or 60 frames, forming partitions one centimetre thick, and containing small bars and cords to support the sheets of parchment paper necessary for the work. The water frames alternate with those of the molasses or syrups. Each frame is pierced by two openings in the interior, giving passage, one to hot water, the other to the syrup, so that, from two contiguous partitions, water is obtained from one, and syrup from the other. The two liquids start from a height of one metre, arrive at the base of the apparatus, and ascend, in order to leave the higher orifice at a temperature of 70° to 80° C. They can also circulate in a contrary direction.

The water is introduced and regulated in such a manner

as to serve for the degree of refining required. Among the results obtained are the following:—

1st. The beetroot liquors treated by these apparatus having yielded results pure enough to be employed in place of water in the melting of raw sugars for refining, one can easily understand the advantage of a like substitution—economy of fuel and direct conversion of the syrup into refined sugar, for the greater part of the products of the beetroot.

2nd. For the syrups of the second drawing the improvement has been more extraordinary; they have given constantly 8 to 10 per cent. of very fine and good sugar, more than the syrups obtained without osmose, and the baking is more easy.

3rd. The syrups of the third drawing, baked without being either filtered or reosmosed, put in the cisterns, and submitted to the action of the turbine, give products of the first quality when taken to the baking oven.

4th. The syrups of these third drawings osmosed give 25 per cent. of their weight of excellent sugar by the turbine, while those not osmosed only render 10 or 12 per cent. of black and pasty sugar.

5th. Lastly, the molasses of the fourth drawings, formerly sent for distillation or used in the manufacture of sugar, are treated now by osmose, and yield from 16 to 18 per cent. of their weight of sugar, No. 10; if they are reosmosed, placed in cisterns, and treated at the proper moment, as much as 10 or 12 per cent. of good sugar can be yet obtained.

The machinery is stopped every second day for washing the interior of the apparatus—first with hydrochloric acid, afterwards with a jet of steam, first applied at La Tour-du-Pin by the advice of the inventor, M. Dubrunfaut. This operation takes about four or five hours. The success of the osmogene was not so apparent until the time when these regulations were scrupulously followed. The irregularities which nearly discouraged the manufacturers were only caused by the want of washing and cleanliness.

One man and a boy suffice to set a group of apparatus at work. All they have to do is to regulate the flow of the two liquids by aid of the cocks. The syrups which flow into the osmogenes are heated to the boiling point of water. The expense in labour, coal, parchment-paper, animal black, mechanical labour for taking down and setting up the apparatus when it is necessary to change the papers, is 2 fr. per hectolitre, or 1 fr. 40 c. per 100 kilogs. The 100 kilogs., giving at least 25 kilogs. of sugar No. 15, require an expenditure of 5 fr. 58 c. per sack, which is a small amount, when we take into account that the produce is worth from 56 fr. to 57 fr. the sack at market price the 54 sack (the No. 12), a price which is also very ill remunerative to the manufacturer. The latter will have a powerful auxiliary in the osmose to compete with the low prices which ruin the native sugars.

Tar, in a thousand different forms, is the pharmaceutical preparation now mostly in vogue. M. E. Guyot has made a special subject of it, and has reason to be proud of the success of his tar liquors prepared in the following manner:—Concentrated tar from Norway 11 kilos., water 20 litres, carbonate of soda 1 kilo.; the whole is then heated in a distilling apparatus in a sand bath. He then takes the liquor which has not passed over the still, and adds a sufficient quantity of water so as to produce 40 litres of liquid. It is then allowed to settle, and the clear part poured over into a barrel. The volatile portions obtained are then added, and the whole well mixed together for some minutes, and left to stand for several days, and then filtered. The result thus obtained is a dark brown liquor, of a strong aromatic taste, mixing perfectly with water, and giving tar water. Thirty-two grammes (one ounce) contain one grain of resinous matter.

Before concluding, I would also point out M. Adrian's cases, which contain an officinal solution of perchloride of iron and magnesium, neutral and unalterable, adopted by the new French Pharmacopœia, p. 182; a medicinal collodion, very adhesive and very elastic, entered also into the new Codex; an excellent quality of cucumber ointment, of which eight tons are sold annually; a granulated vegetable tar, very easily taken internally, and very efficacious; a fluid for bronzing iron and steel; a resinous powder which enables gold to be applied without difficulty to silk, leather, paper, or to tissues in general.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, April 18.

Dr. J. H. Gladstone, F.R.S., Vice-President, in the Chair.

The minutes of the previous meeting were read and confirmed, and a long list of donations to the Society's library announced, and acknowledged by a vote of thanks. Mr. William Phipson Beale, barrister-at-law, Stone Buildings, Lincoln's Inn, was duly elected a Fellow of the Society, but the result of the ballot was adverse to the election of another candidate proposed at the same time. For the first time were read the names of Mr. Robert R. Tatlock, Millhouse, Kyles of Bute; and Mr. Walter William Fiddes, gas engineer, Southernhaye, Clifton; and for the second time were read the following: Messrs. William Gowland and George Robert Gowland, 48, High Street, Sheffield; Mr. John Cargill Brough, journalist, 4, Norman Terrace, Stockwell; Mr. Edward Packard, jun., manufacturing agricultural chemist, Ipswich; Mr. F. W. Peterson, of Her Majesty's Mint, Calcutta, 51, Myddelton Square, London.

Mr. J. Spiller read a paper entitled "*Observations on the Weathering of Copper Ores.*" The speaker quoted several authorities in support of the assertion that copper pyrites and other sulphide ores of copper undergo a slow oxidation on exposure to air and moisture with formation of blue vitriol, the conditions favouring this change being briefly alluded to. The examples of natural oxidation, to which reference was specially made, were instances of the conjoint action of water and air upon certain Devonshire ores containing mundic, spathic iron, and mica-schist in admixture with the copper pyrites. Their assay gave from 8 to 9 per cent. of metallic copper, and the examination further extended to several waste cupriferous materials, or "tailings," containing between 1 and 3 per cent. of the same metal. The ores proper had the following average composition:—

	In 100 parts.
Cupriferous pyrites . .	36 to 40
Spathic iron	10 ,, 14
Sand, mica-schist, &c. . .	54 ,, 46

The "tailings" proved to contain, besides sand and schist,

Cupriferous pyrites . .	3·7 to 12·1 per cent.
Spathic iron . . .	12·0 ,, 23·9 ,,

By the action of hydrochloric acid the two last-named minerals were separated, and the spathic ore was found to contain, as usual, much carbonate of lime, and nearly 10 per cent. of the carbonate of manganese.

The watercourse in which the washing and commercial preparation of the above-mentioned ores was conducted showed no trace of sulphates, and but a very small proportion of mineral constituents—chiefly carbonate of lime—when collected above the mines; but immediately below the workings the dissolved impurities were greatly increased—from 4·5 to 15·3 grains per gallon—and there was besides much pulverulent copper ore held in suspension. The quality and amount of the contaminating ingredients varied at different times, but chloride of barium never failed to produce with the water an immediate precipitate, and the sulphates of copper, iron, manganese, alumina, and lime were detected. The cupric salt rose on one

occasion to 1·25 grains per gallon, and the sulphate of manganese amounted to 1·38 grains; whilst from a depositing pit close to the mines "green vitriol" was found in solution to the extent of 55 grains per gallon. The sandy deposits from the bed of the river likewise contained metalliferous substances having their origin in the mines, and which were distinctly visible as shining yellow or iridescent particles by the aid of a microscope. Copper ore was detected to the amount of 18 grains in the pound (avoirdupois) of dried sand at a distance of about one mile from the works, and the proportion rose to 97 grains of copper pyrites per lb., midway between this point and the mines.

From a consideration of the nature of the metallic salts introduced into the stream, Mr. Spiller was led to examine more closely the products of oxidation furnished by samples of the moist ore after they had remained in his possession for upwards of a year, and during that interval been subject to the influence of the air, by being preserved in bottles covered with a double fold of paper, which permitted of the evaporation of moisture from the contents. A specimen of ore which at the date of collection gave up to water no appreciable amount of soluble sulphates, and certainly no trace of copper, when examined a year afterwards was found to yield a mixture of sulphates in the proportion of 40 grains per lb. of ore.

In these metallic salts the presence of copper was apparent by its blue colour and other characteristic reactions; and there was much sulphate of manganese, besides a small quantity of protosulphate of iron. A sample of the refuse mud, collected from the stream near the mines in January of last year, and freely exposed to the air during an interval of fourteen months, furnished as much as 64 grains per lb. of a mixture of metallic sulphates upon washing with water. The greatest part of this consisted of sulphate of manganese, with the corresponding salts of copper, iron, and alumina, and a trace of sulphate of lime—ingredients identical with those detected in the water after it had passed the mines and been contaminated by the operation of washing the ores.

The author said that Mr. Church had been associated with him in conducting some of the experiments of recent date. That gentleman had also studied the influence of various metallic salts upon the growth of meadow grasses and other forms of vegetable life. Mr. Spiller exhibited samples of the ores and natural products treated of in the paper, and concluded his account with the following general remarks:—

From these experimental observations, it follows that not only is blue vitriol a product of the action of air and moisture upon crude samples of copper pyrites ore, but that secondary reactions usually occur in consequence of the presence of spathic iron, aluminous schist, and other associated minerals, the metallic bases of which become converted into sulphates at the expense of an oxidised portion of the sulphur contained in the ore. It will be necessary to adopt some precautions (the use of chalk or lime, for instance) to avert the baneful influence of such metallic salts upon land irrigated by, or naturally subject to, the overflow from streams thus impregnated with mineral poisons. And finally, these experiments disclose the existence of vast quantities of waste cupriferous material which it would be very desirable to utilise.

The Chairman moved a vote of thanks to Mr. Spiller for his communication, and said that the facts stated had, he believed, an interest for several Fellows whom he saw in the room.

Mr. David Forbes said he could corroborate Mr. Spiller's experiences from the results of his own observation. Some copper ores underwent a very rapid oxidation on exposure to air. There was, for instance, a Spanish pyrites ore from which the copper could be extracted by merely being laid upon an inclined plane, watering occasionally, and treating the washings from it with scrap iron to effect the reduction of the sulphate formed. It was curious to notice the modified action under some circumstances in the mine itself, particularly in the formation of metallic copper, which sometimes appeared as pseudomorphs with the hexagonal form of arragonite. The speaker had satisfied himself of the reality of the occurrence of these natural changes by being enabled to repeat them in the laboratory. The presence of so much as 2·9 per cent. of copper in a sample marked "tailings" was unusual, and must be taken as evidence of careless working, since most Cornish copper ores submitted to washing contained originally less than this amount of metal.

Mr. F. Field had watched the oxidation of copper pyrites ore in Chili, and had noticed not only the formation of considerable amounts of the sulphate, but, under the peculiar circumstances of a seashore locality, also large quantities of the oxychloride of copper, artificial "atacamite." In a horizontal flue, or culvert, the sandy floor of which was impregnated with sea salt, he found, in 1858, no less than 27 cwts. of cupriferous material—the result of a single year's accumulation—and of this a large proportion was a mixture of brochantite and atacamite.

Professor A. H. Church wished to add a few words to the statement made by Mr. Spiller. The speaker had made special experiments with the copper ores in question, by placing them in the state of fine powder upon grass and other herbage, and keeping them properly moistened with water of undoubted purity, and yellow spots were formed upon the blades of grass wherever the particles of copper pyrites rested, and eventually the whole plot was blighted and killed. The effect of sulphate of manganese was found to be very prejudicial to vegetation, and the sulphate of iron was known to be so. After describing the physical features of the locality, and the manner in which the meadows were irrigated, Mr. Church stated that he had independently traced the copper ore in the stream at great distances below the mines; he had likewise satisfied himself regarding the existence of cobalt; but of manganese there was so large an amount that its presence could be clearly demonstrated, in a fluid drachm of the mine water, by evaporation to dryness and fusion of the residue with caustic soda and a little chlorate of potash. Mr. Spiller and himself had particularly noticed the luxuriant growth of water-weeds in the pure stream above the mines, whilst at the workings and everywhere below their existence was abruptly terminated, and all the fish had disappeared.

Mr. Spiller was glad to find that his short paper had elicited so ample and interesting a discussion. In reply to Mr. Forbes he would simply remark that the richest of the three samples of "tailings," of which analyses had been given, formed portion of a considerable deposit which might eventually be submitted to a more careful dressing, and then worked as an ore.

A short paper entitled "*Oxidation of the Acids of the Lactic Series*," and a preliminary note "*On Limited Oxidation with Alkaline Permanganate*," by Messrs. E. T. Chapman and Miles H. Smith, were read by the first-named author; and the Secretary also read a paper from Dr. F. Crace Calvert, "*On the Presence of Soluble Phosphates in Cotton Fibre, Seeds, &c.*"

[Pressure of more important matter compels us to defer a report of these communications until next week.]

The meeting was then adjourned until Thursday, May 2.

ACADEMY OF SCIENCES.

(From our own Correspondent.)

April 15, 1867.

MM. Coulvier-Gravier and Chapelas resumed in a note their observations of twenty years (1845-1856) on the displacement in the night and morning, and from the east to the west, of the resultant of the falling stars, and have laid

down the following laws, to which we call the attention of M. Schiaparelli:—1st. The displacement of the resultant is greater in proportion to the size of the meteorites. 2nd. The displacement is not the same at different epochs: it is greatest from January 1 to May 1; the minimum is between May 1 and September 1; its average amount is on September 1, October 31. 3rd. In January, March, and May, the resultants approach nearest to the south and south-west, and which constitute bad weather; from June to October the resultants meet towards the east, this being the period of fine weather; lastly, in October, November, and December, the resultants redescend to the south and south-west. 4th. The resultants of the red stars and globular stars occur between the south and the west, which idea leads to the considering of them as forerunners of winds and tempests, which always come from that direction.

M. Delosse presented a coast map of France.

M. Fizeau returned to the subject of the abnormal contractions and dilatations of iodide of silver. He finds in the case of this salt, whether in its amorphous or crystalline state, that the action of heat established by him is reversed; its dilatation is negative, contracting instead of expanding on the increase of temperature. But this negative dilatation is not quite the same in the amorphous state, in the state of compressed precipitate, as in the crystalline state; −0·00000137 in the first case, −0·00000139 in the second.

The Reverend Father Secchi, of the Roman College, gave an account of his stellar spectroscope and the different spectra of several classes of stars. He explains by the differences of temperature, or by the effect of absorption, the variation in intensity of certain lines—the line F, for example, one of those of hydrogen, which are determined by the comparison of the stellar spectra.

Father Secchi presented also the drawings and figures of his meteorograph, an admirable instrument which registers automatically the temperature, barometric pressure, the amount of water in the atmosphere, the force of the wind, &c.; it is one of the marvels of the Paris Exhibition. The reverend *savant*, lastly, communicated an observation tending to prove that iron heated to a white heat is transparent.

April 22.

Messrs. J. Tyndall, Charles Brooke, and Hirst, of the Royal Society of London, were present at this meeting.

M. Sanson maintained, against the opinion of M. d'Arrest, that a teratological accident could not produce a new race, and persisted in denying the existence, in South America, of a flat-nosed bovine race, called natá or niata, and which has disappeared.

M. Lecoq, of Clermont-Ferrand, corresponding member, communicated a curious observation upon the intense vibratory motion in the heart of an oloclasia, a very remarkable alimentary plant, from its great round naked roots. The vibrations, from 110 to 120 per second, are communicated to the box, and a little bell attached to the plant is set ringing. M. Lecoq asks whether this is not a transformation of heat into mechanical motion.

M. Tresca read a second part of his researches on the flowing of solids through simple or multiple, circular, polygonal, and lateral orifices, and described a great number of interesting particularities which confirm the results of his former experiments, and undoubtedly prove that the molecules of substances of the stiffest nature in appearance possess the property of moving independently generally in parallel directions. The flowing takes place in concentric zones or calottes more or less elongated, which sometimes are folded together, &c.

M. A. Milne-Edwards read the *résumé* of a memoir of a new family of "*Rongeurs*," called by him *Sophromys Imhausii*, brought from Aden by M. Imhaus. This little animal has lived for two years in the Garden of Acclimatation. It differs much from other known species—by the prolongation of the hind legs, which are terminated by veritable hands; by the numerous granulations, regular and symmetrical, on top of the head; by the lateral prolongation in an arched form of the sinciput, which descends on both sides as far as the cheek bones, and other differences.

Mr. Sterry-Hunt, of Quebec, Canada, the celebrated geologist, recently elected a Fellow of the Royal Society of London, read a paper on the formation of gypsums and dolomites. Already, in 1859, he had shown—1. That the mutual reaction of bicarbonate of lime and sulphate of magnesia gave rise to sulphate of lime and bicarbonate of magnesia. 2. That all the carbonates of magnesia arose from the decomposition of the primitive silicates, aided by atmospheric carbonic acid. 3. That a double anhydrous carbonate of lime and magnesia, having the composition of dolomite, can be produced by heating slowly, from 120° to 150° C., a mixture of lime and hydrated carbonate of magnesia. 4. That there are dolomites which contain greater or less proportions of magnesia, whether in the stale of hydrated carbonate of magnesia or in the state of simple hydrate. It is evident, then, that the loss of carbonic acid of the solutions of gypsum and bicarbonate of magnesia explains the partial decomposition of the former.

NOTICES OF BOOKS.

Familiar Lectures on Scientific Subjects. By Sir John F. W. Herschel, Bart., K.H., &c. London: Alexander Strahan, 56, Ludgate Hill. 1867.

The reading public hold very generally in high estimation such authors as Faraday, Hugh Miller, Prof. Forbes, and Sir John Herschel, who, bearing names second to none in their respective branches of scientific knowledge, occasionally left all technical language behind them, and familiarly introduced to the person of ordinary intelligence the latest triumphs of all-conquering science.

The benefits accruing to science from such familiar lectures, as long as they are not too familiar (for science has a dignity to maintain), are very great; by their means the sphere of scientific interest is enlarged, and listeners are not unfrequently converted by them from simple admirers to energetic workers in a boundless field. These are not the only reasons that might be urged with advantage to the people who continually are talking about a little knowledge and its dangers. Familiar lecturers on scientific subjects contain in their roll the noblest names of the day, whether they appear at St. Martin's or St. James's Hall, or at working men's lectures at the School of Mines.

In this roll of heroes there is no more worthy knight than Sir John Herschel, and we hope that the essays in the volume before us will be placed side by side with the "Chemistry of a Candle" for generations yet to come. We say essays, for each of the fourteen lectures is perfect in itself, and most varied subjects are treated in the most diversified manner—*e.g.*, "Hermogenes and Hermione discussing Atoms" (Lecture XI.), and Lecture X., a critical essay "On the Yard, the Pendulum, and the Metre." The preface gives us full details of the causes of this dissimilarity of matter and treatment. The first three essays, "On Earthquakes and Volcanoes," "The Sun," and "Comets," appeared in *Good Words*, being founded on lectures given to a village audience in a schoolhouse. "Weather and Weather Prophets," "Celestial Measurings and Weighings," "Light" (Essays IV. to IX.), from the same source. Lecture IX. "On Sensorial Vision," was delivered at the Leeds Literary and Philosophical Society, in 1858; Lecture X., "On the Yard, Pendulum, and Metre," to the Astronomical Society of the same town, 1863; and the author remarks with the true spirit of a watchful foe, in referring to legislation on the subject, "The agitation in favour of which only sleeps for the

present, in the view of allowing the public mind to familiarise itself with the idea under a permissive act—to be assuredly brought forward again with renewed activity, and under a more intense and prolonged pressure (to be met by a more concentrated and determined resistance) on no distant occasion." We never did Sir John Herschel the injustice of imagining that he was not thoroughly earnest in the matter. The dialogue on atoms, so widely known to all readers, appeared some time ago in the *Fortnightly Review* for the first time, and was followed by the essay on the origin of force.

The last essay, on target-shooting, is fresh, we believe; it certainly is not a familiar lecture, and a familiar lecture-reader, if he began the book at the end, would certainly never reach the beginning. The paper immediately preceding it, treating "of the absorption of light by coloured media, viewed in connexion with the undulatory theory," is already in part familiar to our readers, it being the substance of a paper read before the Section of Physics of the British Association, at Cambridge, 1853, none of the heat vibration views of later date being discussed. This is, we suppose, another "familiar lecture," but we will not quarrel with the title of the book, the mass of matter being indeed familiar, especially at the outset; but as we go on we progressively pass from *Good Words* to the *Fortnightly*, thence to local scientific societies, afterwards a step further to the Physics Section, British Association, till the climax of erudition is attained at the end of the book by the estimation of skill in target-shooting. It requires a good physical and chemical scholar to do justice to this work, as a whole, such is the author's versatility, and so great are his powers of putting a thing that seemed most abstruse in the clearest light. We shall take further opportunities of noting the details of some of the papers of greater interest; at present we will notice only the book generally. It forms a handsome volume, and is very neatly printed, being the kind of work that schoolmasters so like to come across for class prizes, for which purpose we can recommend no book more strongly.

A debt is owed to Sir John Herschel by every philosopher, who has to the present time always been subject to some awful quotation or other from Swift as a final answer to anything advanced as being a scientific truth; and as the adventures in Lilliput, Laputa, and Brobdingnag are quite outdone by the discoveries of modern science, a little scepticism is allowable. But Swift has never before been so thoroughly answered, as far as his attack on the Royal Society is concerned, as now, p. 62—"After all, Swift's idea of extracting sunbeams out of cucumbers, which he attributes to his Laputan philosophers, may not be so very absurd;" for it is the actual identical heat which the sun puts into the coal while in form of living vegetation, that comes out again when it is burnt *as* coal in our grates and furnaces.

Swift's idea may seem strange to us. "Not more so, at least, than some of his other Laputan speculations, such as calcining ice into gunpowder, or moving vast locomotive masses by magnetism; both which feats have, in a somewhat altered form of expression, been accomplished (as in the explosion of potassium when laid upon ice, and the movement of a ship by electro-magnetism); or than his plan for writing books by the concourse of accidental letters and selection of such combinations as form syllables, words, sentences, &c., which has a close parallel in the learned theories of the existing races of animals by natural selection."

The style of the essays at once shows the authorship; and the profundity of the scientific remarks made—or, rather, the philosophical light by which all things are illumined, to be found on every page—becomes at times quite amusing. With quotations to illustrate this, we conclude our notice, strongly recommending the reader to add to them for himself.

On p. 19 we read, "The earthquake rolls away, and industry, that balm which Nature knows how to shed over every wound, effaces its traces and festoons its ruins with flowers. It seems, no doubt, terrible, awful, perhaps harsh, that 20,000 or 30,000 lives should be swept away in a moment by a sudden and unforeseen calamity; but we must remember that sooner or later every one of those lives must be called for, and it is by no means the most sudden end that is the most afflictive." Such thoughts must be a great consolation to the inhabitant of a volcanic district, and are certainly quite satisfactory to such as do not live in the neighbourhood. Herod might so have reasoned with the mothers of the slaughtered innocents. A typical case is given, p. 42, at Terra Nova—"Altogether about 40,000 people perished by the earthquakes, and *some* 20,000 more of the epidemic diseases produced *by want* and the effluvia of the dead bodies."

CONTEMPORARY SCIENTIFIC PRESS.

[Under this heading it is intended to give the titles of all the chemical papers which are published in the principal scientific periodicals of the Continent. Articles which are merely reprints or abstracts of papers already noticed will be omitted. Abstracts of the more important papers here announced will appear in future numbers of the Chemical News.]

Jahrbuch der Kaiserlich-Königlichen Geologischen Reichsanstalt. October-December, 1866.

The Ruhmkorff Coil.—Congress is about to do justice to an American inventor, Dr. Charles G. Page, of the United States Patent-office, by an act authorising him to apply for and receive a patent for his induction apparatus and electric circuit breaker, known as the "induction coil," the merit of which was awarded by the Emperor of France and a French Commission to Ruhmkorff, without knowledge of Dr. Page's invention.—*American Artisan.*

NOTICES OF PATENTS.

2025. *Producing Gas for Illuminating Purposes.* J. Hamilton, Glasgow. Dated August 6, 1866.

A method by which the heavier carburetted oils serve as a basis for greater illuminating power.

2026. *Improvements in the Manufacture of Carbonates and Bicarbonates of Soda and Potash, the Soluble and Insoluble Silicates of Soda and Potash, and Muriatic Acid, from Chlorides of Sodium and Potassium.* W. E. Newton, Chancery Lane, London.

The process begins by the action of nitric acid on the sodic and potassic chlorides. At a high temperature the nitric acid is replaced by silicic acid, so getting the various silicates, the more of the soluble ones the better; the nitric acid is recovered and used again, and the silicates are in turn decomposed by carbonic acid under strong pressure. By stopping at the various stages, the different products are obtained.

2043. *Production of Sal-Ammoniac in a Commercial Form.* P. Spence, Newton Heath, Lancashire. August 8, 1866.

The salt will by this method be prepared in compressed cakes for economic use.

2066. *Improvement in the Utilisation of Chloride of Manganese (residue of Manufacture of Chlorine) in the Manufacture of Peroxide of Manganese, Chlorine, and Hydrochloric Acid, and in Apparatus for the same.* W. Clark, Chancery Lane, London.

By means of the apparatus used, a manufacturer's compound is regained from a waste product, the recovered manganese peroxide being used, converted into chloride, and again used, *ad infinitum*. No residue of the manganese chloride is left, it is stated.

2067. *Apparatus for Manufacturing Illuminating Gas, and producing Bone Black and other valuable Residuum.* J. T. Ensley, New York, U.S. August 11, 1866.

This abandoned process, which probably would not be commercially successful, is applicable for many purposes, and would answer were the residuum sufficiently valuable. A retort is used with a fire chamber and smoke pipe. A chamber is placed in the retort, opening only outwards, to receive a charge. A cylinder fits this chamber accurately, being open at one end for the charge; any number of these may be provided. When charged the open end of the cylinder is closed by a well-fitting cover, held closely applied to the cylinder by a pressure screw. From this air-tight chamber the gases are carried by a pipe, and are purified by a communicating system of vessels, and so pass to the gasometer.

Communicated by Mr. Vaughan, F.C.S., Patent Agent, 54, Chancery Lane, W. C.

CORRESPONDENCE.

Natroborocalcite.

To the Editor of the Chemical News.

Sir,—Referring to a paper on Natroborocalcite in the last number of the Chemical News, by Professor How, I beg leave to remark, in justice to Dr. Kraut, that this gentleman has not overlooked Dr. How's priority in reference to his formula for the above-named mineral. He has, on the contrary, treated the history of the analysis of that mineral so fully that I thought myself excused from expatiating on it again. When calling the formula in question "Kraut's formula," I did not at all mean to contest the undoubted claim of Dr. How to have established it first in some instances, but I referred to Dr. Kraut's having subsequently endeavoured to prove its general validity from many other analyses. He even succeeded, in fact, in eliminating some analyses which seemed at first to contradict How's formula. Nevertheless, this has not been possible in the case of the sample first analysed by me, and then by Dr. Kraut himself, as explained at the close of my paper in the Chemical News of February 22, 1867. I am, &c. G. Lunge, Ph.D.

South Shields, April 20.

Reduction of Weighings to a Vacuum.

To the Editor of the Chemical News.

Sir,—In your paper on the adjustment of chemical weights, published in the last number of the Chemical News, you say, "The value of the weights thus given is their weight in *air* of the ordinary pressure; it therefore becomes necessary to reduce them to what they would be worth in a vacuum;" and in the table you state that the 1000 grain weight weighs, *in vacuo*, 1000·1462 grains. This I quite understand; but on turning to Professor Stas's researches on the atomic weights,* I find, where he has reduced the weights in air to weights *in vacuo*, there is a slight diminution. For instance, in the table given on the page referred to, he says, "weight of the silver in air, 91·4655 grammes; weight of the silver reduced to a vacuum, 91·4620 grammes." How is this to be accounted for? I am, &c.

J. Lloyd Smith.

Dublin, April 23.

[The downward pressure which a body exerts when suspended in a fluid, (air or water), is equal to its absolute weight, *minus* the weight of the fluid which it displaces. This applies to the weights as well as to the body weighed. *In vacuo* masses of matter exert the maximum downward pressure. The equation in air is —Weight of body, *minus* weight of air it displaces = weight of weights, *minus* weight of air they displace. If, therefore, the substance weighed be *lighter* than the weights it is weighed against, the correction for the vacuum will increase the weight of the mass. If, however, the substance weighed be *heavier* than the weights, the correction for the vacuum will require a subtraction to be made from the apparent weight of the mass in air. On turning to the table quoted by our correspondent (Chemical News, iv. 228) it will be seen that the vacuum-weight of the *silver* is slightly less than its air-weight, but the vacuum-weight of the *chloride* of silver is greater than its air weight. The inference from this is that Professor Stas used brass weights, which would be intermediate in specific gravity between silver and chloride of silver.—Ed. C.N.]

* Chemical News, vol. iv. p. 228, &c.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Silicium Compounds, some New (Si = 28, O = 16).—C. Friedel and A. Ladenburg. Wöhler and Buff prepared an inflammable silicic chloride by the action of chlorhydric acid gas on crystallised silicium, but did not obtain it in a state of purity. The authors have repeated the experiment, and have isolated $SiCl_3H$, boiling between 34° and 37°·5, the vapour of which mixed with air explodes on contact with an ignited body. Chlorine converts it into silicic chloride. Bromine does not act on it at the ordinary temperature, but at 100° the mixture becomes colourless. Absolute alcohol which has been digested with ethylic silicate and distilled reacts with it to form

$$\left.\begin{matrix}(SiH)'''\\(C_2H_5)_3\end{matrix}\right\}O_3,$$

boiling between 134° and 137°, bearing to the inflammable chloride the same relation as that existing between ethylic silicate and silicic chloride. It differs from ethylic silicate by greater inflammability, and by the property of disengaging hydrogen when mixed with alcoholic solution of ammonia. If sodium be introduced into it, silicic hydride, SiH_4, 2 volumes, is evolved; the sodium remains bright, and the reaction at present is unintelligible. This gas is not spontaneously inflammable, at least at ordinary temperatures. $SiCl_3H$ in contact with water at 0° seems to form $Si_2H_2O_3$.

We may compare $SiCl_3H$ with CCl_3H chloroform, $SiH(C_2H_5O)_3$ with Williamson's $CH(C_2H_5O)_3$ tribasic ethylic formate, SiH_4 with CH_4 methylic hydride, and $\left.\begin{matrix}SiHO\\SiHO\end{matrix}\right\}O$ with $\left.\begin{matrix}CHO\\CHO\end{matrix}\right\}O$ formic anhydride? These analogies suggest a convenient nomenclature, silicichloroform, tribasic ethylic siliciformate, siliciformic anhydride.—(*Comptes R.* lxiv. 359.)

Benzylic Bromide (C = 12).—C. Lauth and E. Grimaux. Bromtoluol from toluol and bromine (*Bull. Soc. Chim. Paris*, 1866, 347) resists potassic acetate, ammonia, alcoholic solution of potash, and fusing potash. Kekulé's benzylic bromide, from benzylic alcohol and bromhydric acid, differs, according to his views, from bromtoluol, as shown by these formulæ:—

C_6H_4Br,CH_3	C_6H_5,CH_2Br
Bromtoluol.	Benzylic bromide.

By the action of bromine vapour on toluol vapour, benzylic bromide boiling at 202° is obtained, capable of interchanging with potassic acetate to form potassic bromide and benzylic acetate, and, like benzylic chloride, when treated with nitric acid giving benzoylic hydride. No bromtoluol is produced. Beilstein's view, that by operating on hot toluol chlorine or bromine is introduced into the lateral chain, and in the cold into the principal chain of carbon atoms, is thus confirmed. The authors propose, in like manner, to examine xylol (dimethyl-phenyl) and coal-tar cumol (trimethyl-phenyl).—(*Bull. Soc. Chim. Paris*, 1867, 108.)

Oxidising Properties of Benzol Homologues.—M. Berthelot. Toluol, like oil of turpentine, when shaken with indigo solution, decolorises it. Benzol does the same, but very slowly. Cumol, xylol, and styrol are in this respect intermediate between toluol and benzol. Naphthalene has no action.—(*Bull. Soc. Chim. Paris*, 1867, 109.)

Hydrocarbons, Compounds of, with Potassium (C = 6).—M. Berthelot. Coal-tar cumol, and probably cymol, acetylene, naphthalene, anthracene, retene, &c., and phenyl, form compounds with potassium, and, less definitely, with sodium. The properties of all these compounds are nearly identical. To prepare the naphthalene compound, potassium is gently fused under naphthalene, the black crust removed from the surface of the metal as quickly as it forms; the naphthalene remaining after the potassium is entirely converted is dissolved out with

benzol; a black powder ($C_{20}H_8K_2$) remains; no hydrogen is evolved. Water decomposes this compound, with production of a hydrocarbon ($C_{20}H_{10}$?) more fusible than naphthalene. If the naphthalene and potassium be surheated, a red-brown, very sparingly soluble hydrocarbon is produced, the solution of which presents powerful orange fluorescence, recalling Fritzsche's chrysogene. Great analogies exist between these compounds and those resulting from the action of potassium and sodium on chlor- and brom-derivatives of hydrocarbons.—(*Bull. Soc. Chim. Paris*, 1867, 111.)

Silicic Acid, Isomeric States of (Si=44·5).—E. Fremy. Silicic acid is derived from quartz, metasilicic acid from silicic fluoride. Alkalic silicates differ from the corresponding metasilicates in their greater tendency to crystallise; they do not, on heating, become insoluble in water, as do the metasilicates; the hydrate separated from them by acids becomes, on ignition, insoluble in alkaline solutions; that from the metasilicates being, under similar circumstances, easily soluble. Both acids are tribasic, and capable of forming primary, secondary, tertiary, and intermediate salts. Hydrated silicic acid forms, with acids, compounds much more stable than the analogous metasilicic acid compounds. Metasilicates, when treated with excess of alkali, change to silicates. The most easily crystallisable alkalic silicate is $(SiO_3)_2,3NaO,27HO$, described by Fritzsche. The type of tertiary silicates is $SiO_3,3MO$; that of tertiary metasilicates $(SiO_3)_3,3MO$. Fremy concurs with Chevreul, who thinks that when a hydrated acid is changed by heat to an isomer the change is due to an allotropic modification of the anhydride, the disengagement of water being a secondary phenomenon.—(*Comptes R.* lxiv. 243.)

Valerylene, New Derivatives of (C = 12).—Reboul. The compounds herein described confirm the former view that valerylene is capable of giving rise to two series of bodies—a group of unsaturated compounds apt to unite with H_2,Br_2 or HBr, and a group of saturated compounds. The bodies described are the monochlorhydrate $C_5H_8\left\{\begin{matrix}H\\Cl\end{matrix}\right.$, dichlorhydrate $C_5H_8\left\{\begin{matrix}H_2\\Cl_2\end{matrix}\right.$, monoiodhydrate, mono- and di-acetates, mono- and di-hydrates. Although valerylene gives rise to a double series of compounds analogous to those derived by Wurtz from diallyl, yet the latter does not appear to be homologous with the former, for the differences between the boiling points of the hydrocarbons and of their respective derivatives are inconsistent with homology.—(*Comptes R.* lxiv. 284.)

Argentic Iodide, Effect of Heat on.—H. Fizeau. Former experiments proved that potassic, sodic, ammonic, and argentic chlorides, potassic and argentic bromides, potassic, mercuric, plumbic, and cadmic iodides, expand more when heated than even zinc or lead (*Comptes R.* lxii.); but argentic iodide, fused or crystallised, contracts as its temperature rises. The fused iodide contracts very regularly between − 10° and + 70°; with equal regularity it expands on cooling.—(*Comptes R.* lxiv. 314.)

Argentic Iodide, Note on.—H. Ste.-Claire Deville. We are reminded of some singular reactions of iodhydric acid and silver. Silver dissolves with disengagement of hydrogen in iodhydric acid solution with production of IH,IAg crystallisable, a solution of which, in contact with silver leaf and air, deposits crystals of argentic iodide. Argentic chloride is decomposed with great evolution of heat by iodhydric acid solution, chlorhydric acid being evolved. Silver leaf immersed in mercuric iodide vapour combines with iodine, and mercury is liberated. Recent determinations prove that amorphous argentic iodide is more dense than fused iodide, and that fused iodide is more dense than crystallised iodide.—(*Comptes R.* lxiv. 323.)

Atacamite, Artificial.—H. Debray. Tribasic cupric nitrate heated to 200° with concentrated sodic chloride solution, gives atacamite as a green crystalline powder; an ammoniacal solution of cupric sulphate heated to 100° with concentrated sodic chloride, deposits all the copper as atacamite in a pulverulent crystalline form. The presence of alkalic chlorides is indispensable. Basic cupric carbonate, sulphate, or phosphate gave no satisfactory result.—(*Bull. Soc. Chim. Paris*, 1867, 104.)

Nitrotoluol.—A. Kekulé. Researches in progress show that Jaworsky's nitrotoluol is the veritable one, and that the liquid is not isomeric with the crystalline nitrotoluol, but a mixture of this with some other bodies.—(*Bull. Soc. Chim. Paris*, 1867, 105.)

Benzylic Chloride (C=12, O=16).—C. Lauth and E. Grimaux. Cannizzaro proved the identity of chlortoluol with benzylic chloride. To prepare this body, excess of toluol vapour at 110—140° is acted on by chlorine; the production of higher derivatives appears even then unavoidable. Heated for two hours with its weight of nitric acid (1 part acid, 10 parts water), benzylic chloride gives benzoylic hydride; or, to avoid secondary action of aqua regia produced by chlorhydric acid set free in the reaction, plumbic nitrate and carbonic dioxide may be used. Benzylic chloride boiled with fresh plumbic oxide gives benzylic alcohol; heated with its equivalent of potassic phenylate, it gives phenyl-benzyl ether decomposed by a high temperature, crystallisable, melting at about 40°; heated to 115° in sealed tubes with rosaniline or rosanilinic chloride in alcoholic solution, a very fine violet colouring matter insoluble in water is produced. Several treatments with benzylic chloride are necessary. Among the higher chloro derivatives found in the first reaction is chlorobenzol. This explains Beilstein's formerly expressed opinion that chlorobenzol is dichlortoluol, refuted by Naquet by the preparation in the cold of dichlortuol; the relative proportions of these isomers depend probably on the temperature employed.—(*Bull. Soc. Chim. Paris*, 1867, 105.)

MISCELLANEOUS.

New College in Dublin.—The following paragraph, quoted from the *Observer*, will interest some of our readers. It will be observed that there are two chemical chairs, one at 300*l.* and the other at 200*l.* per annum. We are given to understand that they are both filled up:—"The arrangements of the Lords of Council on Education and of the Lords of the Treasury respecting an intended new College of Science in Dublin, provide for the conversion of what has been known as the Museum of Irish Industry into such college. It will have ten professorships, seven of which already exist. The professors of applied mathematics, and mechanism, and of descriptive geometry, machinery, and surveying, will have 400*l.* per annum salary, rising to 500*l.* These are new chairs. The professor of applied chemistry will have 300*l.* per annum, and will have to instruct the royal exhibitioners free of charge. Other professors will teach in such subjects as physics, general chemistry, botany, zoology, geology, mineralogy and mining, and agriculture, at salaries of 200*l.* per annum. The government of the college will be vested in a council of professors and a dean of faculty. The secretary of the present committee of lecturers will be secretary to the Council, at 400*l.* a year; and the curator of the museum will be librarian also, at 300*l.* per annum. There will be nine royal exhibitions of 50*l.* each, tenable for three years, three becoming vacant each year. Sir Robert Kane's office as Director of the Museum of Irish Industry is abolished, and he gets no new office in the College, their lordships regretting that there is no one of them which they could offer to a person of his eminence. The total expenditure upon the Irish College of Science will be about 7000*l.* a year."

Bismuth.—A discovery has recently been made in South Australia of a lode of bismuth, samples of the metal being now to be seen at the Melbourne Exchange, to which place it has been sent from the neighbouring colony. This metal is very valuable if found in quantity, and it is stated that the lode discovered contains abundance of rich stuff, but, being situated about 200 miles in the interior, some serious difficulties in the cost of carriage have been encountered. Trouble was also experienced in getting the metal smelted, but a quantity of it was sent to England in ingots a few days ago, and it is expected the supply will be kept up.—*Melbourne Age.*

Pure Caustic Soda.—We have received from the Magnesium Metal Company, Manchester, a specimen of the fused hydrate of sodium which they advertise as prepared from metallic sodium. It appears to deserve the title "chemically pure." It dissolves in water, leaving no residue. The solution, acidified with nitric acid, gives no turbidity with silver or barium salts; hydrochloric acid produces only a barely perceptible effervescence when added to the alkaline liquid, and on evaporation to dryness, and ignition, the chloride of sodium dissolves in water, leaving no residue whatever. Special tests show the absence of phosphoric acid and alumina.

Priestley Commemoration.—At the commencement of this month the scientific people of Birmingham assembled to do honour to the memory of this great philosopher, in whom they possess a special interest, from the fact of most of his discoveries having been made, and most of his works published, in that town. They acknowledge also the disgrace that their unworthy treatment of him is to the town. Dr. Priestley was appointed to the pastorship of the New Meeting at Birmingham, with the stipulation that his week should be allowed for scientific research, ministerial duties being reserved for Sundays only. The chairman, on this occasion, remarked that the worthy doctor's personal habits were peculiar, for he "rose at 6 o'clock in the morning, breakfasted at 8, dined at 1, took tea in the evening, and afterwards enjoyed himself amongst one of the happiest families," &c.—truly a most eccentric character he must have been! With such interesting details a memoir so called was filled up. A just tribute was paid to the Lunar Club, to which Priestley, Watt, Boulton, Galton, Darwin, and Baskerville belonged—a worthy association of great names. It would be well if such clubs existed now in the various large cities of Great Britain, independently of societies and associations. At the conclusion of the proceedings it was resolved "That it was desirable that there should be a public memorial (to be called the Priestley Memorial), and that the council be respectfully requested to consider the best means of securing the same." May this not prove an early April resolution! We learn, too, that there was also an interesting collection of Priestley's relics exhibited. The laboratory of Priestley still exists in Birmingham: the restoration and preservation of this would be a very graceful and fitting memorial.

A SUGGESTION TO MANUFACTURERS AND INVENTORS.

Those who read advertisements must often be struck by observing that, while one person advertises for something of which he stands urgently in need, another advertiser often offers for sale, in the same column, precisely what advertiser No. 1 *is trying to obtain. In a similar way it is continually found that a manufacturer is in want of a process that some chemist wishes to dispose of. It also often happens that a difficulty is found in carrying out some manufacture which could easily be overcome by a short investigation by a competent chemist, and, indeed, in many cases a difficulty which appears insuperable to the manufacturer would prove a mere bagatelle to the chemist.*

Impressed with this idea, we wish to call the attention of manufacturers and others to the ease with which they may place themselves in communication with scientific men by the simple means of forwarding their wants to us under the form of "Notes and Queries."

We propose, therefore, if supported by our readers, to insert without charge, but of course briefly, and in the form of queries, the essential points of any letters of inquiry which may be sent to us.

In many cases it is evident that the answers may be published for the benefit of the public generally; in other instances the querist may be placed in communication with the chemist or inventor who has the required information to impart.

The plan thus briefly indicated may also be made to include announcements by inventors of processes or discoveries they may wish to dispose of.

It is, of course, to be distinctly understood that the Editor of this journal does not in any way vouch for the correctness of the information given, nor for the good faith of his correspondents.

ANSWERS TO CORRESPONDENTS.

*** All *Editorial Communications* are to be addressed to the Editor, and *Advertisements* and *Business Communications* to the Publisher, at the Office, 1, Wine Office Court, Fleet Street, London, E.C. *Private* letters for the Editor must be so marked.

An Ignorant Student.—*L. Mond.*—In our next.

A Subscriber.—Magnesian limestone or dolomite occurs in beds of considerable thickness and great extent in the north of England. It is also met with in the Isle of Man and in Fifeshire.

S. G. Melbourne—The little modifications and improvements you refer to have been in contemplation for some time, and will in all probability be commenced with our next volume. A series of articles on the other subject of inquiry are now in preparation by the first English authority, and will shortly appear in the Chemical News.

Standard Thermometers.—We have received several communications on this subject, but in its present form we think the discussion has proceeded far enough. The subject, however, is one of considerable importance to chemists, and it is far from our desire to close our pages to it. If any manufacturer or experimentalist will communicate the results of experiments, we shall be glad to give them publicity; but a statement of opinions insufficiently supported by facts has ceased to possess interest.

A Dyer.—No satisfactory results have been obtained in depositing gold from its solutions upon fibrous matters. One of the most promising methods consists in saturating the fibre with solution of chloride of gold, and then exposing it to phosphuretted hydrogen gas, by which the metallic lustre is developed. The result is, however, too irregular to be of use.

J. Y. S. has lined a cistern with hydraulic lime cement, and fancies that the water has been rendered considerably "harder" by its action on the cement; he wishes to know of a remedy. We would suggest that the whole of the inside of the cistern be washed over with a solution of silicate of soda, and allowed to dry thoroughly before the water is put in. Carbonate of soda and the excess of silicate will impregnate the water at first, but this will last for a few days only.

Communications have been received from D. Wilkinson, J. B. Dancer, S. Mellor, W. Bywater, Subscriber (Perth), W. F. Barrett (two communications), J. Browning, J. F. Shaw; Belding, Keith, and Co.; D. Waldie, Sydney Gibbons, Dr. Adriani, Rev. B. W. Gibsone, J. Sylvester (with enclosure), J. Robinson, Dr. Lunge, W. B. Giles, J. Hargreaves, M. J. Stark (with enclosure), Robertson and Scott (with enclosure), J. Jeffery, W. H. Leigh.

Books Received.—Ophthalmic Review; Journal of Materia Medica; Moniteur Scientifique; Photographs of Eminent Medical Men, No. 2, vol. ii.; La Manifattura Ginori a Doccia.

ENGLISH DISCOVERERS AND FRENCH ACADEMICIANS.

A communication on the estimation of copper, from M. de la Follye, was recently brought before the French Academy by M. Pelouze. The author says that, in attempting to estimate copper by Pelouze's process (precipitation by a standard solution of sulphide of sodium), he met with certain difficulties which led him to try another process, and he ultimately decided upon adding a standard solution of cyanide of potassium to an ammoniacal solution of the copper which was to be determined. M. de la Follye calls this "only a modification of the excellent method of that eminent chemist," Pelouze; and as that eminent chemist himself presented the paper, we may assume that he admitted the substantial accuracy of the statement.

We are so accustomed to see English discoveries rediscovered by French chemists and brought before the Academy of Sciences as undoubted novelties, that in general we refrain from drawing attention to this unfairness. It appears to be one of the stages through which an English discovery must pass before it obtains Continental recognition; but for several reasons we cannot allow this instance to pass over without animadversion. Every chemist will at once perceive that the new process of M. de la Follye is absolutely identical with that of Henry Parkes, published in the *Mining Journal* in 1851. Owing to its neatness, convenience, and general accuracy, it has become almost universally employed in the commercial analysis of copper ores, and we venture to say that there is scarcely a laboratory in Europe in which Parkes's process has not been more or less used. In all standard works on analysis, English and German, Parkes's process stands side by side with Pelouze's process; and were it not that an English writer generally remarkable for his literary accuracy has appeared to acquiesce in M. de la Follye's pretensions, we should say that it was utterly inconceivable how any chemist could venture to publish so old and well-known a process as original.

We are glad to see that this discreditable attempt at appropriating Henry Parkes's well-earned laurels has met with an indignant protest from E. F. Dürre, of Berlin, in the *Berg. und Hüttenmännische Zeitung* for March 22. He says that there is "nothing rare in their Western neighbours ignoring foreign merit altogether; but in such a case as this, when a well-known process is brought, as a new discovery, before an important learned Society, by a man of wide-spread reputation and acknowledged ability, it becomes the duty of every one not to content himself with the mere rectification of the error, but to enter a loud protest against such a claim."

After pointing out the utter groundlessness of MM. de la Follye's and Pelouze's pretensions, Herr Dürre concludes by saying that it is necessary that this circumstance be rightly appreciated, to show how cautious one must be in respect to a French communication, even when it is brought before the Academy of Sciences by one of its members.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On the Determination of Soda in the Assay of Potashes, by M. Graeger.

Commercial potashes generally contain soda. To determine the proportion by volumetric assay, we must know the quantity of pure alkaline carbonates contained in the substance to be assayed. For this object the author dissolves 6·911 grammes of the potash to be assayed in 100 c.c. of water, weighs the insoluble portion, and determines in one part of the solution the quantity of chlorine (chloride of potassium), in another the quantity of sulphuric acid (sulphate of potash), determinations which may be made with standard solutions. The estimation of the alkalies is effected on 10 c.c. of the solution by means of normal nitric acid; and from the quantity of acid added the relation of soda to potash may be calculated, as the total quantity of alkaline carbonates is known by subtracting from the total weight of substance taken the weight of the insoluble matter of the chloride and sulphate of potash.

To assist in the employment of this method, the author has drawn up a table giving the amounts of carbonate of potash and carbonate of soda corresponding to the quantity of normal nitric acid necessary for their saturation:—

KO,CO_2. Grammes.		NaO,CO_2. Grammes.		NO_5. C.C.
1·00	+	0.00	require	14·47

If, for example, it is found that the crude potash taken contained 5·1134 grammes of pure alkaline carbonate, and it required 79 c.c. of normal nitric acid, the proportion 5·1134 : 1·0 : : 79 c.c. : x will give the quantity of normal acid ($x = 15{\cdot}45$ c.c.) which one gramme would have required, and on reference to the above table it is found that 15·45 c.c. of normal acid correspond to 0·22 of carbonate of soda and 0·78 of carbonate of potash, or 78 per cent. — *Journal für praktische Chemie*, t. xcvii. p. 496 (1866), No. 8.

On the Preparation of Pure Chloride of Ammonium, by J. S. Stas.

(*Continued from page* 194.)

III. Chloride of Ammonium obtained by means of the Ammonia produced by the Reduction of Nitrite of Potassium.—To procure nitrite of potassium, I had recourse to Stromeyer's process. I heated to redness one kilogramme of nitre with four kilogrammes of lead in a small cast-iron crucible. When the vivid incandescence which at first ensued was over, and the mixture sufficiently cooled, I washed it in boiling water. I then, by means of a solution of hydrosulphate of potassium, eliminated the lead from the solution of nitrite. After removing the sulphide of lead and concentrating the remaining solution, I added fifteen litres of a solution of caustic potash of a specific gravity

of 1·250. This mixture was poured into a globe of a capacity of twenty-five litres, placed in a sand-bath, and which contained a mixture of three kilogrammes and a half of granulated zinc, deprived of its carbon by fusion with a mixture of carbonate of soda and nitre* and a kilogramme and a half of iron, which, after having been oxidised by calcination in contact with air, had been reduced by hydrogen.

The globe communicated, through a large bent tube, with an arrangement for washing and condensing the ammonia to be produced. This arrangement consisted of—1st, a large tubulated retort placed upon a furnace and containing a certain quantity of pure water, into which the tube coming from the globe was plunged; 2nd, a large Woulff's flask with three tubes containing half a litre of pure water; 3rd, a Woulff's flask containing water acidulated with hydrochloric acid, for the purpose of retaining the ammonia carried over by the current of hydrogen, which is produced very freely when the reduction of the nitrite takes place and the liquid in the globe is boiled.

Before distilling the liquid in the globe, I allowed the materials to react during seventy-two hours, so as to reduce as completely as possible the nitrite of potassium into ammonia and oxide of potassium and zinc. After this I boiled the liquid gently for two hours, keeping the water boiling in the retort and cooling that contained in the large Woulff's flask intended for the condensation of the ammonia.

It is indispensable to boil the liquid contained in the globe *very gently*, as it bubbles up violently by the disengagement of the hydrogen at a high temperature. I recommend chemists who wish to procure absolutely pure ammonia by this means to distil the liquid decanted from the mixture of zinc and iron. As I ascertained in a subsequent trial, after the reduction of the nitrite into ammonia has taken place, the decanted liquid may be distilled without the least difficulty.

The ammoniacal solution produced smells exactly similar to the ammonia extracted from chloride of ammonium treated with aqua regia, or from sulphate of ammonium treated while hot with a mixture of sulphuric and nitric acids.

These three ammonias, though identical with each other, differed very considerably as to smell from the pure ammonia obtained from commercial chloride or sulphate of ammonium, both of which contain compound ammonias, that give it a disagreeable smell, whilst the smell of pure ammonia is simply pungent. I have already mentioned these facts in my previous work on the same subject.

To transform the dissolved ammonia into chloride, I passed through the solution a current of pure hydrochloric acid until the liquid was nearly saturated. I then evaporated the saline liquid on a water-bath, and finished drying it on a stove. This chloride of ammonium was of a dazzling whiteness. I proceeded to *sublime it in a large platinum retort* purified at a red heat with chloride of ammonium. To exclude the air from the retort, I passed through it, during the volatilisation, a very slight current of dry ammonia. This precaution is absolutely indispensable, since, in the presence of air and of heated platinum, the vapour of sal ammoniac will readily produce nitric acid and afterwards chlorine.

The volatilised chloride of ammonium covered the upper portion of the head of the retort, in the form of a compact, crystalline, colourless, transparent ring half a centimetre thick, whilst the head and neck were filled with chloride of ammonium, as a fine dust of a dazzling whiteness. Both exhaled a strong ammoniacal smell.

Before being used to determine the proportional ratios, the compact and the powdered chloride were heated in the same apparatus in which they were weighed, until they gave off vapours of sal ammoniac, so as to eliminate the last traces of condensed ammonia.

* Zinc may be deprived of carbon by fusion with 5 per cent. of its weight of litharge. The alloy of zinc and lead thus produced is as effectual in reducing nitrite of potassium in the presence of iron as pure zinc. In the presence of dilute sulphuric and hydrochloric acids, it disengages hydrogen with great facility.

Preservation of Sulphuretted Hydrogen Solution in the Laboratory.

At the last meeting of the Pharmaceutical Society of Paris, M. Lepage, of Gisors, brought forward a process which he has adopted for preserving solutions of sulphuretted hydrogen. All chemists know that this useful reagent cannot be preserved long in aqueous solution. The author has adopted for some years an artifice which enables sulphuretted hydrogen solution to be kept for twelve or fifteen months with scarcely any loss of strength. Instead of using water, he saturates a mixture of equal parts of pure glycerin and water with sulphuretted hydrogen gas, and uses it in the ordinary manner. None of the reactions are interfered with in the least, whilst the solution possesses almost perfect stability. The dilute glycerin dissolves less gas than distilled water will; representing the solubility in the latter liquid by 100, that in the former will be 60.

Glycerin likewise prevents solution of sulphide of ammonium from becoming coloured, and M. Lepage believes that it has a similar action on the sulphides of potassium and sodium.

TECHNICAL CHEMISTRY.

On the Discovery of Sulphate of Strontium in Upper Silesia, and its Application in Agriculture, by Geo. Lunge, *Ph.D.**

The following fact may not be quite uninteresting to such of the readers of this journal as work in agricultural chemistry. In a locality in Upper Silesia there is found a stratum of an earthy mass, similar in colour to chalk, but crystalline under the microscope, which had been taken by the farmers of the neighbourhood for a kind of marl containing gypsum. Many hundred tons of it have been used for years as a manure, and with the best success. Quite lately Professor Krocker, of Proskan, got a sample of this mass, and found it to contain—

	Per cent.
Sulphuric anhydride	36·00
Strontia	46·57
Lime	1·80
Magnesia	1·60
Potassa	0·50
Chloride of sodium	0·25
Carbonic anhydride	1·40
Phosphoric anhydride	0·10
Silicic anhydride	2·10
Alumina and ferric oxide	3·60
Clay, sand	4·28
Moisture and organic substances	1·80
	100·00

The mineral is, then, essentially sulphate of strontia,

* Communicated by the author.

and it is remarkable that it has proved of some value as a manure, notwithstanding the very slight solubility of that body, and although it cannot be supposed that strontium can absolutely substitute calcium in the plants.

On the Waste of Materials in the Alkali Manufacture, by James Hargreaves.*

In the manufacture of carbonate and hydrate of soda from its sulphate there is a very considerable loss of material, which renders the actual produce very considerably less than is indicated by theory. This loss of course varies in different manufactories, according as care and skill are exercised to reduce it, or the work is carried on carelessly and at haphazard. The reduction of this loss is not only of individual, but of national importance, inasmuch as the glass, soap, paper, and other manufactures having the most immediate influence on civilisation and comfort, depend for their existence and extension on a large and cheap supply of this alkali. The usual method of estimating the alkali produced from the crude sulphate of soda or "salt cake" is to multiply the weight of soda ash produced from every 100 tons of salt cake by the percentage of alkali contained in it, and divide these integers by some standard number—say, 48, 50, or 52, which gives the number of tons of ash of the standard strength from each 100 tons of salt cake used. Theoretically, 100 tons of salt cake containing 96 per cent. of sulphate of soda, or 42 per cent. of the base, should produce 84 tons of soda ash of 50 per cent. The following list of practical results shows how different manufacturers fall short of the theoretical yield :—

	Ash from 100 parts of salt cake.	Standard percentage of ash.	Equal to alkali produced per cent.	Total loss per cent
Soda-ash	75	50	37·5	10·72
	70	52	36·4	13·44
	70	50	35·0	16·66
	66·66	52	34·67	17·46
	70	48	33·6	20·00
	66·66	50	33·33	20·65
Caustic soda	57·5	60	34·5	17·86
	55	60	33·0	21·20
	50	60	30·0	28·57

The sources of this loss are as follows :—

1. **By soda salts carried mechanically into the flues and chimney.** — I am not aware that any attempts have ever been made to ascertain the quantity thus carried away, but it must be very considerable, more than is generally suspected. Where salting pans are used, and the hot gases from the black-ash furnace are passed over the crude soda solution to partially carbonate and dry it to "salts," this salt and the "red liquor" drawn along with it generally contain from 0·25 to 1 part of sulphate of soda to every 100 parts of available alkali, more than is contained in the crude soda liquor when run into the pan; the proportion varying with the elevation of the furnace bed, the intensity of the draught, and the mechanical division of the sulphate. But this does not represent the whole of the sulphate thus carried away unutilised, the finer particles being carried beyond the pan into the flues and chimney. In the "finishing furnace," where the "black-ash salt" is heated to dull redness, to expel water, burn out carbonaceous matters, and oxidise the sulphide of sodium present, converting it into sulphate of soda, there is also a small quantity carried away in this manner, as is shown by the glazing of the bricks and deposit of alkaline dust in the flues.

2. **By volatilisation of sodium salts.**—A more considerable loss of material is sustained by the volatilisation of sodium, principally as sulphide and carbonate. The workman generally prefers to work with his furnace very hot, so as to get out his complement of "balls" as soon and with as little labour as possible. The temperature of the furnace is generally below the boiling point of any of the sodium salts present, but when a rapid current of hot gas is passing over and given off from the materials, these salts are absorbed and carried off as vapour, the action of the hot gas in this case being analogous to that of a current of air in drying up water or other volatile fluids when far below their boiling-points. When the door of the lower bed of the furnace is opened while the temperature is high, a white cloud, containing sulphate and carbonate of soda, may be seen rising from the bed. The sulphate is produced by the oxidation of volatilised sulphide, in consequence of the in-rush of cold air through the door, which at once oxidises the sulphide and condenses the alkaline vapours by reduction of temperature. The practical difficulties of the work have so far prevented the estimation of this and the former sources of loss, but comparison of the materials put into and drawn from the furnace leave no doubt that it is very considerable, and varying with the temperature at which the furnace is worked. There is no advantage except that of saving labour and time to the workman in having the temperature higher than is necessary to reduce the sulphate of soda, and cause the sulphide of sodium and carbonate of lime to react on each other. When the temperature is maintained too high, there is not only a great loss by volatilisation, but the increased quantity of fuel used for the purpose is thrown away, the furnace is prematurely worn out, and there is formed at very high temperatures an allotropic sulphide of sodium, which does not react on the lime present in the charge.

3. **By combination of soda with the materials of the furnace.**—This is another, but comparatively small, source of loss. The bricks, &c., taken from the furnace while undergoing repair hold in combination a considerable amount of soda, being in some pieces 6 per cent. and upwards, but in an insoluble condition, and therefore unavailable. The fused sodium salts which have filtered into the interstices of the furnace are also of no practical utility.

4. **By the formation of insoluble compounds of soda,** which, by rendering impossible the extraction of the alkali by lixiviation, still further diminishes the yield. The small coal, which is used as a reducing agent, invariably contains more or less ash, varying from 1·5 to 8 per cent. Of this ash silica and alumina form a large proportion, seldom less than 80 per cent. of the whole. The salt cake contains from 0·12 to 0·5 per cent. of silica and alumina, and the limestone from 0·2 to 3 per cent. These form with soda a compound silicate, which is sparingly soluble in a solution of caustic soda and sulphide of sodium. When the crude soda solution is oxidised, and the sulphide converted into hyposulphite, sulphite, or sulphate of soda, or when it is exposed to a temperature of 212° F., the alumino-silicate is precipitated. In the oxidising apparatus described in the Chemical News, No. 340, the precipitate is in the form of a white powder; and in oxidising towers, where the solution is oxidised by running it over pieces of coke, to expose a large surface of the fluid to the action of the atmosphere, the alumino-silicate is deposited on the coke, filling up its interstices, and if not frequently disturbed by taking the coke out at the bottom of the tower

* Communicated by the author.

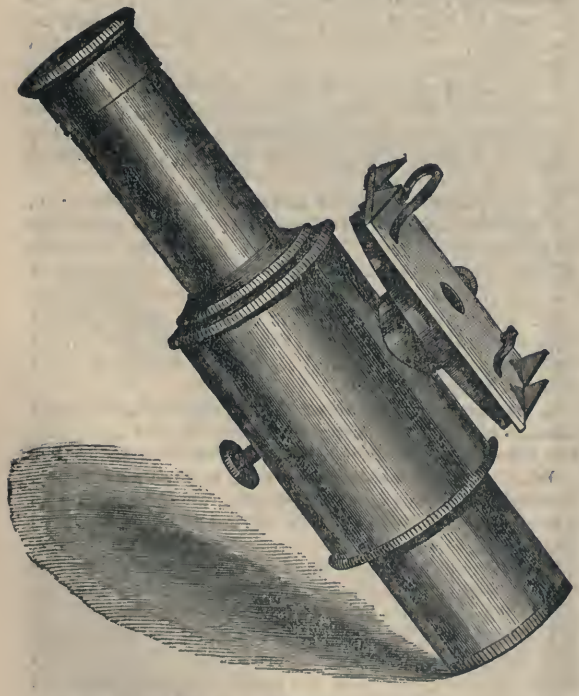
washing and returning it to the top, the whole is in time converted into a firm cohesive mass. Another compound silicate of soda and lime is formed when the silica is in excess of what is required to form the alumino-silicate, and is quite insoluble. The loss from this cause is variable in proportion to the quantity of alumina and silica introduced along with the materials used and the quantity of these substances taken from the bricks of the furnace.

(To be continued.)

PHYSICAL SCIENCE.

On a New Micro-spectroscope, and on a New Method of Printing a Description of the Spectra seen with the Spectrum Microscope.

IN the CHEMICAL NEWS for April and May, 1865,* Mr. Sorby, F.R.S., described his application of spectrum analysis to microscopical investigations, and especially to the detection of blood stains. For the purpose for which it was intended, this arrangement was excellent, but in general practice it was in some respects inconvenient. Mr. Browning has recently made for Mr. Sorby a modification of the spectroscope, which is intended to slip into the eye end of a microscope instead of the eyepiece. The instrument is shown in the accompanying figure. It



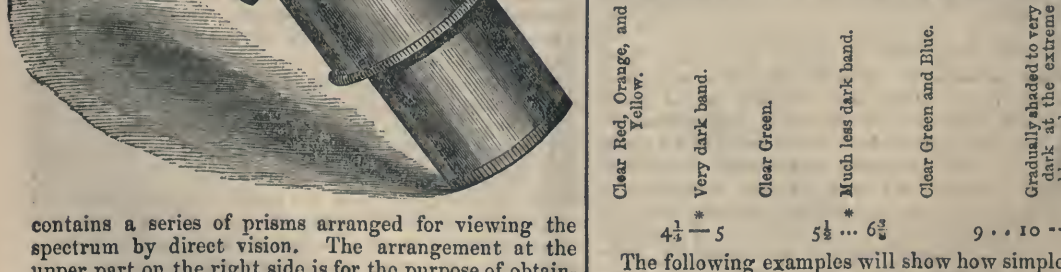
contains a series of prisms arranged for viewing the spectrum by direct vision. The arrangement at the upper part on the right side is for the purpose of obtaining a supplementary spectrum from any object whose spectrum it is desired to compare with that of the object placed on the stage of the microscope. This object may be either a solution of permanganate of potash in a small sealed tube, a cobalt blue glass, or anything else which will furnish a standard spectrum for comparison. There are milled heads with screw motions to adjust the focus of the different parts of the spectrum, and to open and shut the slit vertically and horizontally. Powers of from half an inch to $\frac{1}{20}$th may be employed, and by using a binocular microscope the object may be brought into the field, and examined in the ordinary way through one tube, whilst its spectrum may be observed and compared with that of a standard light by means of the other tube. The object may be illuminated either by transmitted or reflected light, and any of the ordinary accessories may be used for this purpose, such as a chromatic condenser, side reflector, Lieberkuhn, &c.

Mr. Sorby has also introduced a standard spectrum, which he proposes should be used as a scale in all descriptions of spectra, as seen by the spectrum microscope. Mr. Sorby has been good enough to communicate to us the following description of this valuable method:—

The scale adopted is an interference spectrum, produced by a plate of quartz ·043 inch thick, cut parallel to the principal axis of the crystal, and placed between two Nicol's prisms. In this the whole visible space is divided by dark bands into twelve regular divisions, having in all parts the same relation to the physical properties of the light. These are counted from the red end towards the blue, their centres being reckoned as 1, 2, 3, &c., and the thickness of the plate is so adjusted that the sodium line exactly corresponds to $3\frac{1}{2}$. The intensity of the absorption is expressed by the following types:—

Not at all shaded		Blank space
Very slightly shaded	. . .	Dots with wide spaces
Decidedly shaded	. . .	Dots closer together
More shaded	...	Very close dots
Strongly shaded, but so that a trace of colour is still seen	---	Three hyphens close
Still darker	—	Single dash
Nearly black	——	Double dash

Except when specially requisite, only the symbols . . . --- — are employed for the sake of simplicity, and then as signs of the relative rather than of the absolute amount of absorption, and it is assumed that there is a gradual shading off from one tint to the other, unless the contrary is expressed. This is done by means of a small vertical line over the figure (see No. 11), which shows that there is a well-marked division between them. Definite narrow absorption bands are indicated by * printed over their centre. This will be better understood by a description of the spectrum of deoxidised hæmatin.



Clear Red, Orange, and Yellow.
Very dark band.
Clear Green.
Much less dark band.
Clear Green and Blue.
Gradually shaded to very dark at the extreme blue end.
4½ — 5
5½ ... 6⅝
9 . . 10 --- 11—

The following examples will show how simple or more complicated spectra may thus readily be printed and compared. I have chosen solutions of similar tint, in order to show that the spectra of those of nearly the same colour may be very different, or, if analogous, may differ in details, easily expressed by the symbols. The colour of each is given after the name. Nos. 1, 8, 9, 10, 11, 12, and 13 can be kept for a long time, sealed up in tubes, and the rest are easily prepared.

* CHEMICAL NEWS, vol. xi. pp. 186, 194, 232, and 256.

. Cudbear in alum (pink): 3 ..... 8 11 . —

. Colour of elder berries with citric acid (red pink):—

4 . - 5½—8 - - 9 . . . 11 - —

3. Brazil wood with bicarbonate of ammonia (pink):—

$$4\tfrac{1}{2} \overset{*}{—} 5\tfrac{3}{4} \cdots\cdots 8$$

. Logwood with bicarbonate of ammonia (pink):—

$$3\tfrac{5}{8} \overset{*}{—} 5\tfrac{1}{4} \cdots\cdots 7$$

The next four are spectra of blood, produced by the successive addition of the various reagents, as in detecting fresh stains.

5. Fresh blood (pale scarlet):—

$$3\tfrac{1}{2} \overset{*}{—} 4\tfrac{3}{8} \quad 4\tfrac{3}{4} \overset{*}{-} 5\tfrac{3}{4} \quad 7 \cdot \cdot 8 - 9—$$

6. Citric acid then added (pale brown):—

$$1\tfrac{5}{8} \overset{*}{\cdots} 2\tfrac{1}{4} \quad 4 \cdots 8 \cdots 9 --- 10—$$

7. Ammonia then added (pale brown):—

$$3\tfrac{5}{8} \overset{*}{\cdots} 4\tfrac{3}{8} \quad 4\tfrac{7}{8} \overset{*}{\cdots} 5\tfrac{5}{8} \quad 7 \cdot \cdot 8 --- 10—$$

8. Deoxidised hæmatin, from blood stain two years old (pink):—

$$4\tfrac{1}{4} \overset{*}{—} 5 \quad 5\tfrac{1}{4} \overset{*}{\cdots} 6\tfrac{3}{8} \quad 9 \cdot \cdot 10 --- 11—$$

With these may be compared the two spectra which more nearly resemble those produced by blood than any I have yet seen.

9. Cochineal in alum (pink):—

$$3\tfrac{3}{8} \overset{*}{—} 4\tfrac{1}{4} \cdots 5\tfrac{1}{8} \overset{*}{---} 6\tfrac{1}{8} \cdots 7\tfrac{1}{2}$$

10. Alkanet root in alum (pink):—

$$3\tfrac{1}{4} \overset{*}{—} 4\tfrac{3}{8} \quad 5\tfrac{1}{4} \overset{*}{\cdots} 5\tfrac{3}{4}$$

The following spectra of compounds derived from chlorophyll are as complicated as any I have met with.

11. Normal chlorophyll in alcohol (deep green):—

$$\tfrac{7}{8} \overset{*}{—} 2\tfrac{3}{8} --- 3\tfrac{1}{4} \cdots 4\tfrac{1}{2} \quad 6\tfrac{3}{4} \cdot --- 7\tfrac{1}{2}—$$

12. Ditto, as decomposed by acids, or as found in some leaves (olive green):—

$$1 \overset{*}{—} 2\tfrac{1}{8} \quad 2\tfrac{3}{4} \overset{*}{---} 3\tfrac{3}{8} \quad 4\tfrac{1}{4} \cdots 5\tfrac{1}{4} \overset{*}{---} 5\tfrac{3}{4} \cdots 6\tfrac{3}{8} \overset{*}{---} 7\tfrac{3}{8} \quad 8\tfrac{1}{2} \cdot \cdot \cdot 9\tfrac{1}{2}—$$

13. Ditto, as decomposed by caustic potash, and then by hydrochloric acid (red-green, neutral tint):—

$$\tfrac{1}{4} \overset{*}{—} \tfrac{3}{4} \quad 1\tfrac{1}{8} \overset{*}{—} 1\tfrac{3}{8} \quad 1\tfrac{7}{8} \overset{*}{—} 2\tfrac{1}{8} \quad 4\tfrac{1}{2} \overset{*}{---} 5\tfrac{1}{4} \cdots 9 \cdot \cdot 10—$$

These instruments and methods were exhibited and explained by Mr. Sorby and Mr. Browning at the last *soirée* of the Royal Society, where they excited the greatest interest.

Cleaning Glass.—A method of cleaning glass, which may be useful where other methods fail, is given in the appendix to the second edition of Major Russell's "Tannin Process," published by Robert Hardwicke, Piccadilly. Dilute the ordinary hydrofluoric acid sold in gutta-percha bottles, with four or five parts of water, drop it on a cotton rubber (not on the glass), and rub well over, afterwards washing till the acid is removed. The action is the same as that of sulphuric acid when used for cleaning copper; a little of the glass is dissolved off, and a fresh surface exposed. The solution of the acid in water does not leave a dead surface on the glass, as the vapour would; if a strong solution is left on long enough to produce a visible depression, the part affected will be quite bright. This method is recommended in some cases for cleaning photographic plates, but we should think it might also be useful in cleaning the insides of bottles, flasks, &c., which have got stained through use.

FOREIGN SCIENCE.

(From our own Correspondent.)

Paris, May 1, 1867.

I am now enabled to send you a list of prizes to be awarded by the Society of Encouragement, Paris, and their dates. The aim of the Society is the close alliance between practice and theory. It represents invention, improvement, and application. Every new discovery or invention to ameliorate the state of our national industry emanates from this Society. It makes no distinction between the high-placed theorist and the practical man; those who work in a laboratory, in the study of a *savant*, in a workshop, or as labourers, all are equally welcome and of the same grade. The value of the prizes exceeds 6000*l*. The Society does not confine itself, in their distribution, to industrial matters; it extends its recompenses to individuals. Foremen, workmen in manufacture and agriculture, inventors, pupils of industrial schools, persons invalided by work of hand or brain, receive encouragement, recompenses, and *substantial* aid.

Grand Medals.—Gold medals of 40*l*. to French or foreign inventors who have made the most important discoveries applicable to French industry, to be distributed annually in the following order:—1867, Commerce, bearing the profile of Chaptal; 1868, Fine Arts, that of Jean Gougon; 1869, Mechanical Arts, Prony; 1870, Chemical Arts, Lavoisier; 1871, Agriculture, Thénard; Economical and Physical Arts, Ampère.

Grand Prize of 480*l*.—This is given by the Society to the author of a discovery deemed to be the most useful to French industry.

Prize given by the Marquis Argenteuil.—The same amount as the last, awarded to the discoverer of a special invention or improvement, principally with regard to objects in France which have not been yet able to compete with foreign markets, either as to quality or cheapness.

Prizes for 1868, 1869, 1870, 1871, 1872, 1873, *and* 1874.

Mechanical Arts.—Prize of 120*l*. for the best machines for steam navigation, which, with slight draught of water, can enable the machinery and coaling room to be diminished, and thus increase the available space; 1869.

Prize of 120*l*. for a locomotive able to take a goods-train at the rate of thirteen to eighteen miles an hour, with a minimum of expense of prime cost and combustion of fuel; 1870.

Prize of 240*l*. for a motor engine, from 25 to 100-horse power, burning at the most 1½ lb. of coal of best quality per indicated horse-power, weighing less than 661 lbs., and costing from 12*l*. to 16*l*. per horse-power; 1871.

Prize of 40*l*., founded by the Princess Galatzin, for a hydraulic motor for a small workshop, able to work a shaft representing a force of 6 to 20 kilogrammetres* per second; 1868.

Prize of 160*l*. for improvements to be effected in the mechanical weaving of linen and hempen goods; to be awarded in 1872, in favour of the manufacturer who can produce commercially linen threads of a fineness of 100 metres to the gramme, or hemp threads 15 metres. This must be obtained by an economy of at least 15 per cent. of the motive power, and with such a diminution of temperature that there is little or no steam. The manufacturer must have delivered to commerce at least the value of 800*l*. worth of threads of linen or hemp, according to the above-stated conditions.

Prize of 120*l*. for a file-making machine able to cut all sorts; 1870.

Prize for a practical and economical means of cutting mill-stones, whilst diminishing the insalubrity of this branch of industry; 1869, or, if necessary, 1875.

* A kilogrammetre is a kilogramme (2·205 lb.) raised to the height of a metre in one second.

Prize of 80*l.* for a water-meter, acting under a pressure of from 1 to 5 atmospheres with a temperature of 0° to 100° C., and giving the volume of water to within a hundredth part; 1870.

Prize of 40*l.* for a regulator for gas burners.

Chemical Arts.—Prize of 80*l.* for the best process of making oxygen on a large scale; 1869.

Prize of 120*l.* for the industrial application of oxygenated water.

Prize of 80*l.* for extracting the nitrogen of the air in the form of nitric acid or ammonia; 1869.

Prize of 80*l.* for the economical production of cyanide by the nitrogen of the air; 1871.

Prize of 120*l.* to be awarded (1870) to the manufacturer who shall be the first to produce sulphuric acid, quite free from arsenic, from pyrites.

Prize of 40*l.* for the industrial employment of any cheap and abundant mineral; 1868.

Prize of 40*l.* for the utilisation of the refuse of factories; 1869.

Prize of 40*l.* for the useful application of the newly-discovered metals; 1870.

Prize of 40*l.* for new applications of simple substances, non-metallic; 1870.

Prize of 40*l.* for the discovery of a new alloy useful in the arts; 1871.

Prize of 120*l.* for the artificial production of graphite for the fabrication of pencils; 1872.

Prize of 120*l.* for the artificial preparation of the compact black diamond; 1873.

Prize of 160*l.* for the discovery of processes capable of furnishing, by any organic transformations, useful substances, such as quinine, indigo, alizarine, or cane sugar.

Prize of 160*l.* for the artificial production of fatty acids and of waxy substances.

Prize of 240*l.* for a theory of cast steel founded on certain experiments; 1872.

Prize of 120*l.* for the disinfection of the refuse from the purifying of gas; 1869.

Prize of 40*l.* for a process capable of disinfecting and clarifying, quickly and durably, sewage water; 1868.

Prize of 60*l.* for the discovery of an ink which will not rust metallic pens; 1869.

Prize of 120*l.*, 60*l.*, and 20*l.*, for the employment of boracic acid and borax in the ceramic arts; 1868.

F. Moigno.

PARIS EXHIBITION OF 1867.

(From our Special Correspondent.)

Group VI. — Class 44: Chemical and Pharmaceutical Products—Industry of Colouring Matters extracted from Coal.

This great industrial art, illustrated for the first time at the International Exhibition of 1862 with great *éclat*, has not ceased to develope itself, less, however, in France than in Switzerland and Germany, where the progress has been considerable. With us progress was fettered by the fact that aniline red, the basis of all the other colours, was the exclusive property of the Fuchsine Company, and was, in consequence, a general monopoly. The great problem under these conditions was to arrive by direct process at violet, blue, and green colours without passing through the red; it has at length been resolved for violet by MM. Poirrier and Chappat, jun., of Saint Denis, with the able assistance of their chemist, M. Bardy. The methylaniline and dimethylaniline violets, exhibited under the name of "Paris Violet," are the gems of the chemical section, and have most attracted the attention of practical men, also of the jury, who have awarded them a gold medal.

Before describing this discovery, we may remark that the Fuchsine Company have kept up their reputation, and that the display in their glass case is really magnificent; their sphere of radiating crystals, so sharp and voluminous, of chlorhydrate of rosaniline, along with all the salts of rosaniline, have a wonderful effect. They find a powerful rival, however, in M. Müller, of Basle, who also exhibits a large collection, the principal article being a cup containing a pound of rosaniline so pure that it is almost colourless. We have not found chrysotoluidine or malvaudine except on stuffs of silk and cotton, of which specimens are exhibited by MM. Hucotte and Berryer, also the blues of MM. Girard and Laire, the process of which shall be described presently.

The Paris violet, by M. Poirrier and Chappat, No. 23, Rue d'Hauteville, stall No. 2, is produced from the methylaniline and dimethylaniline which Dr. Hofmann discovered and made known by a process very costly and not put into practice. The celebrated chemist employs as a reducing agent the very volatile iodide of methyl, and this would have entailed a considerable loss if 800*l.* per day were constantly risked—that being the quantity necessary to produce 150 kilogrammes of methylaniline that MM. Poirrer and Chappat send to the market every day. In order to arrive at a remunerative product, they have substituted a cheaper substance, nitrate of methyl, for the iodide; it is by this means that they were able to produce their first *ton* of Paris violet at their chemical works. Still this mode of fabrication was fraught with danger, and was discontinued. Happily, M. Berthelot pointed out a process less dangerous and cheaper, the treatment of ammonia by alcoholic radicals.

To obtain methylaniline or dimethylaniline, MM. Poirrer and Chappat place in contact in a closed vessel, at a high temperature, and under pressure, aniline and hydrochlorate of aniline, or methylaniline and hydrochlorate of aniline; and this process, which has required the construction of special apparatus, the application of means for regulating the reaction in order to obtain at will either methyaniline or dimethylaniline, &c., works at present with perfect regularity; they have even extended, with success, the process towards the preparation of other alkaloids based on an alcoholic radical. There remained yet the means of converting methylaniline and dimethylaniline into violet, soluble in water, as there is no complete success without this condition. New agents had to be searched for, that do not require a too high temperature, in order to produce the reduction, or the return would not be so great, nor the colour so bright or of so decided a shade. They finished by transforming the perfectly pure methylaniline from toluidine into violets of all shades not inferior to those derived from the rosaniline of Hofmann.

MM. Tessié de Mothay and Maréchal, of Metz, exhibit a new process for bleaching fibres, threads, and woven stuffs of cotton, hemp, linen, wool, and silk.

The fibres, threads, and tissues contain two sorts of colouring matters—one soluble, after oxidation, in alkaline lixivia; the other substances inherent to the cellulose, which should be bleached by the oxygen of the air and light, or by chemical compounds able to disengage oxygen in its nascent state.

The methods hitherto employed for bleaching or decolorising tissues depend upon the alternate application of two sorts of agents—1. Oxidising substances; 2. Solvents.

But these methods, perfect as they are in their way, have the following faults:—The employment of an oxidising agent which acts with extreme slowness when it is taken from the atmosphere, or with a destructive combustible power when it is several times placed in a medium containing chlorine or the chlorated compounds, such as the hypochlorites, for example; the use of alkaline solvents which act with extreme slowness in dissolving the quantity of colouring matter altered by the oxidising agents. For these latter the most suitable substitutes are—1. Permanganic acid, produced by the decomposition of the permanganates by means of hydrofluosilicic acid. 2. The alkaline

permanganates, with the addition of chlorides, sulphates, and alkaline fluosilicates capable of forming salts, having for base permanganic acid, at the moment when this acid is decomposed by the fibres; passing, themselves, into a basic state, as is shown presently.

In order to employ practically the oxidising agents and solvents above mentioned, the operation is thus:—

For bleaching stuffs or threads of cotton, linen, or hemp, all the grease or fatty matter is extracted by an alkaline bath. They are then steeped in a solution of permanganic acid or permanganate of soda, with the addition of sulphate of magnesia. Afterwards (fifteen minutes' interval generally) the substances to be bleached are removed and transported either into alkaline solutions or into baths containing sulphurous acid, nitrosulphuric acid, or peroxide of hydrogen.

In the first case the substances are heated to boiling-point in alkaline solutions for several hours until the oxide of magnesia which covers them is partially or wholly dissolved.

In the second case the substances to be bleached are steeped in baths containing either sulphurous acid or nitrosulphuric acid or oxygenated water, until the layer of oxide of manganese, with which they are coated, is entirely dissolved; after this they are washed and resteeped, first in a solution of permanganic acid or the permanganate, afterwards in alkaline solutions or in the solvents above mentioned, and so on till the bleaching is completed.

A bleaching-bath, containing, according to the nature of the fibres or tissues to be bleached, from 2 to 6 kilos. of permanganate of soda, is sufficient to bleach effectually a hundred kilos. of cotton, hemp, or flax, raw or woven.

This method of bleaching is the same for wool and silk, except that the alkaline liquid is a weak solution of soap, and sulphurous acid is alone employed.

The industrial results obtained in the factory of M. Verlay, at Comines (Nord), by the above-mentioned process show that hemp and linen threads are completely bleached without alteration in one day; that their tissues are bleached in three days; that the cost for complete bleaching is on an average 3½d. the kilo. for threads, and 5s. per 100 metres for the woven stuffs.

By the present methods of bleaching, even the most rapid and economical, for all textile substances or tissues, threads require, according to the daylight and weather, at least fifteen days and at most thirty; tissues from thirty to sixty days. Also the cost of bleaching, on the other hand, amounts in similar cases to about 4½d. per kilogramme for threads and 7s. 6d. per 100 metres for tissues.

In order to obtain the practical result which we have just mentioned, new economical processes were necessary to be found:—1. The production of manganate of soda; 2. To transform this manganate into permanganate.

Lastly, we mention that manganate of soda is now prepared and sold at the rate of one franc per kilogramme to bleachers.

Its transformation into permanganate is easily and cheaply made, either by means of sulphate of magnesia, chloride of magnesium, or chloride of calcium.

The following formulæ show the transformation:—

$$3(KO,MnO_3) + 2(MgO,SO_3) =$$
$$= KOMn_2O_7 + 2(KO,SO_3) + 2(MgO,HO).$$

A Quinine Famine.—The following is an extract from a letter from Mr. Colville Barclay, President of Poor Relief Committee of the Island of Mauritius: "The mortality from the effects of fever just now is from 180 to 200 every day throughout the island. All the quinine in the place is finished, and half a dozen bottles received fom Reunion last week were sold at 135 dollars the ounce (27*l.* 10s.). The doctors are using arsenic as a substitute. The Government has sent home for 30 lb. of quinine, as well as to Ceylon and the Cape for all that can be obtained."

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, April 18.

Dr. J. H. Gladstone, F.R.S., Vice-President, in the Chair.

In continuation of our report of last week, we now give an account of the papers read by Mr. Chapman, and of the short communication from Dr. F. C. Calvert.

The first, entitled "*Oxidation of the Acids of the Lactic Series*," by Messrs. E. T. Chapman and Miles H. Smith, asserts that the acids of this series may be divided into two classes, according to the nature of the products of oxidation which they respectively furnish; the first containing hydrogen and an organic radical, giving rise to the formation of aldehydes, whilst the secondary acids, containing two organic radicals, produced ketones. Dimethoxalic acid yielded, on oxidation, acetone and carbonic acid, and ethomethoxalic acid (prepared from the corresponding ether of Frankland and Duppa) gave carbonic acid and methylated acetone, boiling at 82—83° C., and having a fragrant odour, very similar to propione. Of this compound an analysis was made, which furnished results in close accordance with the numbers demanded by theory. Like common acetone, it combines with alkaline bisulphites, but with more energy, evolving a considerable amount of heat, and forming a compound which is very soluble in water. On further oxidation of this substance nothing but acetic acid was produced. Similar results were obtained in the oxidation of diethoxalic acid. The authors recommend a resort to this method for the easy preparation of the ketones, and, finally, propose by this means to investigate problems of isomerism occurring amongst the fatty acids, illustrations of which are sketched in the paper.

The Chairman insisted upon the value of an extended optical method of research carried out in conjunction with the principles indicated by the authors in this communication.

A preliminary note "*On Limited Oxidation with Alkaline Permanganate*," by the same authors, was then read. The authors point out the differences in the products of oxidation of common alcohol by the use of acid and alkaline solutions of permanganic acid; thus, whilst, in the presence of sulphuric or other mineral acid, a mixture of aldehyde and acetic acid is produced, on the other hand, in an alkaline solution nothing but oxalic acid is formed. Lactic acid under like circumstances gave similar results. So that much depends upon the maintenance of unalterable conditions during the progress of oxidation with permanganate of potash, and the authors submit that Truchot's and Berthelot's anomalous results obtained in the examination of amylene are attributable to a want of appreciation on their part of this fact. The authors described a method of distinguishing between tartaric and citric acids, founded upon the circumstance that the latter acid does not carry the reduction further than the green manganate in a strongly alkaline solution, whilst tartaric acid furnishes the brown hydrated binoxide.

The Secretary then read a paper by Dr. F. Crace Calvert, "*On the Presence of Soluble Phosphates in Cotton Fibre, Seeds, &c.*" The author points out the fact that seeds contain relatively more mineral phosphates than other parts of the plants upon which they are borne, and alludes to the common practice of burning off the organic matters before proceeding to search for the phosphates therein contained. From his experiments Dr. Calvert has, however, been led to conclude that the whole of the phosphoric acid or phosphates is merely held mechanically distributed throughout the organic tissue, and in such a condition that they may be wholly extracted by the action of water. Cotton yarn steeped for several hours in

distilled water furnished a solution containing appreciable quantities of phosphoric acid, lime, and magnesia, and quantitative experiments were made upon seven characteristic varieties of cotton, which had been carefully prepared and carded in Manchester, for the purpose of determining the extent to which the phosphates could be removed by washing. The results showed by the uranium process amounts varying between ·035 and ·055 per cent. of phosphoric acid thus dissolved, whilst traces only of this constituent could be detected in the ash left upon burning the washed and dried cotton. Similar experiments made upon wheat, French beans, and walnuts gave like results, much phosphoric acid and magnesia being discovered in the aqueous solution. The author promises to continue these researches and communicate the results.

The Chairman moved a vote of thanks in favour of the authors, and adjourned the meeting as already reported.

ROYAL SOCIETY.

Thursday, May 2, 1867.

At the usual weekly meeting this evening the President read from the chair the names of the following fifteen candidates recommended by the Council for election. They will be balloted for on June 6:—William Baird, M.D.; W. Boyd Dawkins, Esq.; Baldwin Francis Duppa, Esq.; Albert C. L. G. Günther, M.D.; Julius Haast, Esq., Ph.D.; Captain Robert Wolseley Haig, R.A.; Daniel Hanbury, Esq.; John Whitaker Hulke, Esq.; Edward Hull, Esq.; Edward Joseph Lowe, Esq.; James Robert Napier, Esq.; Benjamin Ward Richardson, M.D.; J. S. Burdon Sanderson, M.D.; Henry T. Stainton, Esq.; Charles Tomlinson, Esq.

QUEKETT MICROSCOPICAL CLUB.

The usual monthly meeting was held at University College on the 26th instant, Mr. Ernest Hart, President, in the chair.

Dr. Halifax described his ingenious method of obtaining thin sections of insects, soft vegetable tissues, minute seeds, &c., by immersion in wax, and afterwards slicing them upon the ordinary section table.

Mr. Higgins gave a lengthened and interesting description of the "otolithes" or earbones of fishes, to the study of which he has devoted himself with remarkable industry for the last eighteen years. The result of many thousand examinations of fossil and recent fish has enabled him with positive accuracy to identify species, and in many instances genera. His remarks were illustrated by an extensive series of "otolithes," which were displayed in cases in the room, containing specimens obtained from the largest to the smallest fish, both freshwater and marine.

The meeting, which was attended by upwards of 130 members and their friends, terminated with a *conversazione*.

Eight members were elected.

ACADEMY OF SCIENCES.

April 29, 1867.

(From our own Correspondent.)

The sitting of the Academy was very short to-day.

Sir David Brewster presented the opening discourse which he had made at the Edinburgh Royal Society.

M. Baer, of St. Petersburg, warmly thanked the Academy for having given him the Cuvier prize of 1866.

M. Baumhein, present at the meeting, called the attention of a considerable number of members, particularly M. Fizeau, to a forgetfulness on the part of the commission appointed to award the prize for the determination of the length of the waves of the solar spectrum. He deeply regretted that they had not known the remarkable memoir of M. van der Willigen, director of the Teyler Physical Cabinet at Haarlem, which was more complete than that of M. Mascart in 1866.

M. Dumas read a letter, in which M. Pasteur, at present at Alais, and who is finishing his experiments and observations on the precocious rearing of silkworms, announced an important discovery made by him. The organisms that he terms *corpuscles* are propagated, or at least multiplied, by *scissiparity*. They contain a sort of kernel, which ordinarily presents the first indications of scissiparity. M. Pasteur has examined under the microscope the corpuscles of the internal mucous coats of the stomach and the kernels, at all states of division, commencing, in progress, or terminated.

M. Dumas, in the name of M. Naquet, presented the second edition, in two volumes, of his "Principles of Chemistry founded on Modern Theories." It is a well-written work, quite up to the modern progress of science. M. Dumas, however, reproaches the author with having regarded facts too much in a personal light, and enumerating the results without mentioning the processes. Formerly, said the celebrated chemist, the processes were an important item in the teaching of chemistry: and also he has further remarks to make on this reserve, which he will make on a future occasion.

M. Fremy presented a memoir on "*Phenol*," in which M. Dussard announced that he had succeeded in perfectly and easily producing the phenaphtic acid of Berzelius, and preparing diatomic phenol possessing very remarkable properties, and which will bear the same relation to the monatomic phenol as the glycol of M. Wurtz bears to monatomic alcohols.

M. Henri Sainte-Claire Deville presented a note, by M. Cailletet, on an amalgam of sodium with which he has already obtained considerable success. He called to mind the important results obtained by the modern researches of Messrs. Crookes, Matthiessen, Regnault, &c., on alloys. Mr. Crookes, for example, had rendered great service to metallurgical operations by proving that the addition to mercury of a small quantity of sodium renders incomparably more easy and profitable the extraction of the precious metals.

Mr. Sterry Hunt read the summary of his researches upon certain reactions of magnesian salts and magnesian rocks. The author attacked the theory of MM. Haidinger and Suckow, who explain the efflorescence of sulphate of magnesia by the reaction of sulphate of lime and carbonate of magnesia. He believes that the magnesian silicates which form portion of the dolomites in the environs of Paris are the representatives of the unaltered formation of steatites; that the talcs and serpentines are formed aqueously; that the greensands of the Paris basin are of the same composition as serpentines, &c.

CONTEMPORARY SCIENTIFIC PRESS.

[Under this heading it is intended to give the titles of all the chemical papers which are published in the principal scientific periodicals of the Continent. Articles which are merely reprints or abstracts of papers already noticed will be omitted. Abstracts of the more important papers here announced will appear in future numbers of the Chemical News.]

Bulletin de la Société d'Encouragement. January, 1867.

G. de Claubry: "*Report on Bon's Imitations of Precious Stones.*"—"*Blasting of a Cast Iron Roll by Nitro-glycerine at Rothehutte, Upper Hartz.*"—Putsch and Ziehharth: "*Improved Furnace for Melting Enamel.*"—"*A Method of Gilding Glass.*"—Weber: "*An Account of an Explosion of Picrate of Soda.*"—"*On the Preparation of Aniline Colours in Powder for Printing Carpets, and for Lithography.*"—"*On Colouring Brass.*"—Knaffl "*On Colouring Zinc and Brass Black.*"—Jünemann: "*A new quick-drying Fire and Waterproof Cement.*"—Klezinsky: "*Solution for rendering Fabrics Uninflammable.*"

Le Technologiste. March, 1867.

Soames "*On a Process for Purifying Paraffin.*"—E.

Jacobsen "*On the Use of Rosaniline for Detecting the presence of Free Fatty Acids.*"—"*On the Relative Indications of different Optical Saccharometers.*"—V. Kletzinsky: "*Smechochromasy, a Process of Colouring by means of Coloured Soaps.*"

Stein "*On the Elementary Analysis of Hygroscopic Substances.*"—C. W. Paykalt "*On the Analysis of some Swedish Minerals.*"

NOTICES OF PATENTS.

Communicated by Mr. Vaughan, F.C.S., Patent Agent, 54, Chancery Lane, W. C.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

218. E. H. C. Monckton, Summer Hill, Birmingham, "Improvements in the manufacture of butter."—Petition recorded January 26, 1867.

952. W. E. Newton, Chancery Lane, "An improved process for manufacturing ice and for other refrigerating purposes." A communication from T. S. C. Lowe, New York, U.S.A.—March 30, 1867.

979. J. Storey, and W. E. Bickerdike, Lancaster, and W. V. Wilson, Jubilee Street, Mile End, Middlesex, "A new method of bronzing metallic and other surfaces."—April 2, 1867.

1044. W. R. Lake, Southampton Buildings, Chancery Lane, "An improved mode of embalming or preserving dead bodies and carcases." A communication from G. W. Scollay, St. Louis, Missouri, U.S.A.—April 6, 1867.

1054. C. F. Claus, Middlesbrough-on-Tees, Yorkshire, "Improvements in the manufacture of chlorine."—April 8, 1867.

1064. J. H. Player, Birmingham, "Improvements in the manufacture of phosphorus and in economising residual products of the said manufacture."—April 10, 1867.

Notices to Proceed.

3293. F. W. Reeves, Cambridge Terrace, Notting Hill, Middlesex, and J. B. Muschamp, Pembroke Road, Middlesex, "An improved explosive substance."—Petition recorded December 15, 1866.

3326. L. Schad, Warrington, Lancashire, "Improvements in treating aniline colours for dyeing and printing."—December 18, 1866.

3348. S. Parry, Thackeray Street, Liverpool, "An improved composition for the coating of the bottoms of ships and other vessels."—December 20, 1866.

3433. J. Napier, Salisbury, Wiltshire, "Improvements in the preparation of food of a substance to be employed in the place of malt, and for the medication of food for animals."—December 29, 1866.

211. J. J. Lundy, Leith, Mid Lothian, N.B., "Improvements in the treatment of the residual matters resulting from and obtained in the purification and distillation of mineral or hydrocarbon oils, and also in the treatment of coal-tar and various waste or other alkaline and lime substances, for the purpose of utilising the same."—January 26, 1867.

CORRESPONDENCE.

Cement Cisterns for Water.

To the Editor of the Chemical News.

Sir,—I find among the answers for correspondents in No. 386 of your valuable paper, an excellent suggestion to J. Y. S. Permit me to call your attention to the use of hot coal tar for preventing the contamination of the water by the cement. It is a cheap and effective means of preventing what is complained of, and is not a fancy. Experiments made by Captain de Bordes, of the Netherlands Royal Engineers, and myself, many years ago, have proved that even from hydraulic cement which sets and hardens in a few hours, for days after lime and other salts are dissolved out by pure distilled water in very appreciable quantity. In the kingdom of the Netherlands, in many parts, and especially in portions of the provinces of Zealand, North Holland, and Friesland, no other water than rain-water is in general use for domestic purposes, because, like as at Amsterdam, Flushing, the Helder, and other places, all the water of canals, rivers, &c., is either brackish or decidedly salt. Large cisterns built underground, in order to prevent foul infiltrations of surface water, but which have to be laid entirely in strong cement (hydraulic as it is termed) are used to keep the rain-water for the use of barracks and large establishments. These cisterns are often lined with Dutch glazed tiles, fixed in cement, but it has been found cheaper to simply line the cisterns with cement, and after it is dry to give two coatings of hot coal tar. I suggested lately the same to an engineer, who, having applied it to a cistern of his own in his house, found it to answer perfectly. For a few days the water had a slight tarry taste, which is now entirely gone. I am, &c. Dr. Adriani.

Drilling Glass.

To the Editor of the Chemical News.

Sir,—In the Chemical News of April 19 there is a description, by Mr. Spencer, of the old and well-known method for drilling glass by means of a file wetted with oil of turpentine. Some years ago I read in a German periodical of another means for the same purpose—viz., dilute sulphuric acid—and I found it, on trial, to answer much better than the first. Not only, it appears, is the efficacy of the cutting tool more increased by sulphuric acid than by oil of turpentine, but also, strange as it seems, the tools (files, drills, &c.) are far less rapidly destroyed by being used with the acid than with the oil. I also found it stated that, in the engineering establishment of Mr. Pintus, at Berlin, glass castings for pump barrels, &c., were drilled, planed, and bored, just like iron ones, and in the same lathes and machines, by the aid of sulphuric acid. As to drilling, I can fully testify to the efficacy of that method. Whenever I want, say, a hole in the side of a bottle, I send it, along with some dilute (1 : 5) sulphuric acid, to the blacksmith, who drills in it, with a hand brace, a hole of ¼-inch diameter. This hole is then widened

to the required size by means of a triangular or round file, again wetted with the acid. I also find a great help in the latter when making graduations on litre flasks, &c. There is hardly any smell perceptible during the work, which proves how little the acid acts upon the tools, undoubtedly owing to their being tempered; but each time after use I take the precaution to wash and dry the files at once, and I have so far observed no sensible deterioration in them. Hoping this little hint may be useful to some of your readers, as it has been to me, I am, &c.

G. Lunge, Ph.D.

South Shields, April 20.

Extinction of Fires.

To the Editor of the Chemical News.

Sir,—In papers dated Sydney, February 16, I find an account of a patent taken out by Dr. Bland for a method of extinguishing fires in ships' holds and other confined spaces by means of carbonic acid gas. The patentee states that his attention was directed to the subject by the loss of a ship by fire in 1839, and now, after twenty-eight years of, no doubt, laborious experiments, he brings forth the following original process. He places on the kelson of a vessel a number of barrels containing calcareous minerals, and generates carbonic acid gas by the action of dilute acids supplied by tubes from the deck above. The gas finds its exit by numerous holes bored in the upper part of the barrel. The inventor of this brilliant process invited to his establishment at Woolloomoolloo, Sydney, a number of gentlemen, members of the legislature, &c., to witness the success of his patent, but the result was in keeping with the former details. His apparatus for confining the combustion to a closed space was so clumsily constructed that sufficient air found access to keep up the combustion in spite of the supply of choke-damp generated from whiting spread on "iron plates," not from a barrel.

It is sincerely to be hoped that we are not to be prohibited by letters patent from employing carbonic acid gas, generated in any off-hand apparatus, to extinguish combustion. This patent seems about as novel as the caustic soda process of Mr. J. Roddy, mentioned in the last volume of the Chemical News.

I am, &c. T. B.

Manchester, April 26.

Department of Seience and Art.

To the Editor of the Chemical News.

Sir,—As you have occasionally admitted into your columns strictures upon the operations of the Department of Science and Art, attacking now its supposed procrastination, now its inconsistency, and now its impolicy, allow me to submit to you the accompanying extract from a printed notice, which will show, at least, the generous intentions and liberality of the Council on Education towards its certificated science teachers, and which will, I hope, prove their sincere wish to foster the spread of an intelligent scientific taste among the people. It will also furnish some reply to those who have lately questioned the justice or desirability of retaining a special class of beneficed teachers; for it is obvious that were there no limitation to the number of claimants, such a bounty as that which the Government here offer—viz., of paying the expenses of each certificated master who shall visit the Paris Exhibition—would become impracticable. I believe a score of other good reasons could be given why teachers should conform to rule and submit themselves to examination before benefiting from the national grant; and so far from advocating the abolition of such tests, I, in common with many others, would rejoice to see the already high standard of qualification raised, as it is quite possible that the Department may design—it is time to grumble after we have seen their next May's questions—but I feel that it is absurd to expect the Department to continue to apply their vast machinery to the examination of sometimes a solitary candidate, as was my own case on a certain day last November. I am not surprised that they should meditate making the season of examination of both masters and pupils identical. That the questions proposed to each will be identical is now at least problematical; but were they the same it cannot be supposed but that such an experienced professor as Dr. Hofmann (even with his 1500 candidates) could perfectly discriminate by a series of judicious questions between the proficiency fitting for a teacher and that to be expected from a student; while the grouping together of both classes of men in the same grades, though it may mortify the vanity of incompetent or idle would-be lecturers, is at the same time an additional spur to such as have the pride to excel, from the fear lest distinguished pupils of other schools should be classified as their equals. I beg to subscribe myself as one who, though previously qualified to claim receipt of grants on result, yet preferred to submit to routine and become, after examination, A Certificated Master.

April 26.

"Their Lordships announce to the certificated masters now engaged in giving instruction in schools of science and art connected with the Department, that they will pay to each such master or mistress visiting the Paris Exhibition, the sum of five pounds in aid of their expenses, and to each an additional sum of two pounds for any report or any useful suggestions which any such teacher may make (in respect to his or her duties or teaching) derived from the study of the Exhibition, such report having first been published in any journal, local or otherwise, and afterwards approved by their Lordships. And further, to each of the three best of such reports referring to instruction in science and to each of the three best reports referring to art, my Lords will give respectively the following prizes in addition to the sum above named, namely—for science, for the best report, twenty pounds; for the second best report, fifteen pounds; and for the third best report ten pounds, and the same sums respectively to the three best reports for art."

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Alcohols, Synthesis of (C=12).—A Lieben. It appeared probable that the action of zincic compounds of alcohol radicals on chlorinetted ethers would be limited to the chlorine atoms, and afford the means of passing from one step in the series of alcohols to another. It was necessary, in the first place, to establish the constitution of chlorinetted ethylic ether. It appears that this is best expressed by

$$\left.\begin{matrix} C_2H_3Cl_2 \\ C_2H_5 \end{matrix}\right\} O.$$

By this light the body described by Lieben and Bauer as resulting from the action of zincic ethide on chlorinetted ether has the constitution expressed by

$$\left.\begin{matrix} C_2H_3ClC_2H_5 \\ C_2H_5 \end{matrix}\right\} O,$$

and should be called ethylochlorether. This body, under the action of iodhydric acid, gives ethylic iodide, ethylated ethylic chloride, and ethylated ethylic iodide, which last-mentioned body has the composition and boiling-point of Wurtz's butylic iodide. With argentic acetate it gives ethylated ethylic acetate and butylene, or a remarkably similar isomer of butylene. Ethylated ethylic acetate, when boiled with concentrated potash solution, gives ethylated ethylic alcohol, which is most probably isomeric with normal butylic alcohol, and identical with butylenic hydrate. If it be so, then Kolbe's conjecture that the ——enic hydrates are secondary alcohols is established.

Viewed from the same standpoint, another body which has also been described by Lieben and Bauer as a product of the action of zincic ethide on chlorinetted ether, wherein both chlorine atoms are replaced by ethyl, becomes diethylether,

$$\left.\begin{matrix} C_2H_3.C_2H_5.C_2H_5 \\ C_2H_5 \end{matrix}\right\} O.$$

Iodhydric acid produces, with it, ethylic iodide and diethylated ethylic iodide, and from this we may expect to obtain diethylated ethylic alcohol, a secondary or tertiary alcohol isomeric only with hexylic alcohol. It is easy to foresee the synthesis, on these principles, of an almost endless series of different alcohols.—(*Ann. Chem. Pharm.* cxli. 236.)

Mellitic Acid (C=12).—A. Baeyer gives, by letter, some results of researches undertaken in communion with Scheibler. Mellitic acid is hexabasic; it is benzol in which H_6 are replaced by $(CO_2H)_6$. Heated with lime, it splits into benzol and carbonic dioxide; sodium amalgam adds H_6 to it, with production of a hexabasic acid $C_6H_6(CO_2H)_6$, which is converted by sulphuric acid into a tetrabasic acid, $C_6H_2(CO_2H)_4$, to which body H_4 may be added, and carbonic dioxide again expelled by sulphuric acid, when benzoic acid is finally obtained. To complete the series beginning with $C_6(CO_2H)_6$, and ending with $C_6H_5(CO_2H)$, three members of which have been studied, and to extend the researches on the group beginning with $C_6H_6(CO_2H)_6$, more material is required than the authors can command; they therefore entreat possessors of the rare honeystone to come to their assistance.—(*Ann. Chem. Pharm.* cxli. 271.)

Dinitronaphthalene and Potassic Cyanide. (C=12).—Mühlhäuser. The reactions of potassic cyanide with nitro-compounds having been chiefly studied in the acid representatives of this group of bodies, it seemed necessary to extend the research in other directions, and dinitronaphthalene was chosen as a substance easy to prepare and purify. Pfaundler and Oppenheim, in 1865, made some experiments on the subject, but did not succeed in obtaining decisive results. An alcoholic solution of dinitronaphthalene is mixed with aqueous potassic cyanide solution, reaction occurs in the cold but is advantageously assisted after a short time by gradual heating to boiling. A fine blue-green colour marks the end of the reaction. On standing, the solution deposits the potassic salt of naphtocyamic acid $C_{28}H_{19}KN_8O_{10}$, easily soluble in hot water and in alcohol with a splendid blue colour. Its tinctorial power is very great; it explodes if heated; the baric salt is insoluble in cold water and in ether, easily soluble in hot alcohol; the argentic salt is almost insoluble in hot alcohol or water, and is very explosive. The free acid is uncrystallisable, insoluble in water, dissolving with brownish-yellow colour in alcohol or in a mixture of alcohol and water; it is bibasic. The acid and its salts are scarcely less sensitive to alkalies and acids than cyanin or irisine, for if water be shaken with magnesia, filtered, and mixed with a solution of the acid, the yellowish colour of the latter is immediately changed to bright blue.—(*Ann. Chem. Pharm.* cxli. 214.)

Ethylic Sulphate, Action of Ethylic Iodide and Zinc on (Ba=137, C=12).—A. Claus. Perfectly dry ethylic sulphate was digested with excess of ethylic iodide and granulated zinc; the reaction was fully accomplished at the ordinary temperature. The product is a solid dark-green, resinoid, semi-fusible mass. Water and ether were very gradually added to the contents of the flask until the violent reaction ceased; the ethereal solution, having been separated from the aqueous one, was distilled until the temperature rose above 100°; the retort then contained an oily liquid, in bulk about two-thirds of the ethylic sulphate employed, which, when further heated, began to evolve sulphuric dioxide. When all liquid had passed over, a loss of a quarter had occurred. This experiment was not, therefore, repeated, but the oil was boiled with successive small portions of baric hydrated oxide and water; the solution was saturated with carbonic acid, filtered, and evaporated; finally, crystals of $Ba.C_4H_{10}S_2O_4$ baric ethylsulphite were obtained. No other product of the principal reaction is described, but the fact that the addition of water in the first instance caused a copious deposit of zincic hydrated oxide suggests the formation of an intermediate zincic compound analogous to those obtained by Frankland and Duppa under corresponding conditions.—(*Ann. Chem. Pharm.* cxli. 228.)

Nicotine (C=12).—Dr. C. Huber. When treated with chromic acid, nicotine gives an acid $C_6H_5NO_2$, yielding easily crystallisable salts and azo-compounds. Distillation with lime produces C_5H_5N, an oily base soluble in water. The first reaction also produces another acid richer in carbon, and at least one base. Details will be given at a future time.—(*Ann. Chem. Pharm.* cxli. 271.)

Styrol, Isomeric States of.—M. Berthelot. Styrol from storax possesses a rotatory power on polarised light. That from cinnamates has none. The former is more easily attacked by reagents, and, when mixed with sulphuric acid, disengages more heat than the latter. Polymers of styrol produced by the action of heat or of potassium reproduce at 300° the original styrol, whilst those produced by the action of sulphuric acid distil in part undecomposed, behaving, indeed, as mixtures of distyrol, volatile at about 300°, and more highly condensed and less volatile polymers.—(*Bull. Soc. Chim. Paris*, 1867, 112.)

Coal-tar, Synthetical and Analytical Studies on.—M. Berthelot. The reactions of benzol and ethylene at elevated temperatures give rise to styrol, naphthalene, anthracene, chrysene, and some other constituents of coal-tar, the parent substances being themselves directly derivable from acetylene. Another group of constituents—the benzol series—might be expected to result from the action of formene on benzol; but reaction occurs only at a temperature incompatible with the existence of toluol, and anthracene is produced—a fact not without interest, since toluol is converted by heat into anthracene. Free formene differs therefore from free ethylene in its behaviour with benzol at high temperature. To obtain formene and benzol in presence of each other and nascent, a mixture of sodic acetate and benzoate was heated. A small quantity of toluol and a mixture of probably higher benzol homologues were obtained. The synthesis of toluol involves that of toluidine and of numerous other coloured coal-tar derivatives. The group of constituents which may be represented by aniline was studied in that member. A mixture of benzol and ammonia passed through a red-hot tube produced small, but unmistakable proportions of aniline. The oxygenated bodies—phenol, &c.—will be commented on at a future time. With respect to the analysis of coal-tar, cumol at a red heat gives rise to precisely the same series of hydrocarbons as contained in that complex mixture.—(*Bull. Soc. Chim. Paris*, 1867, 113.)

Thermo-chemical Conditions of Pyrogenic Reactions.—M. Berthelot. Ethylene combines readily at a high temperature with hydrogen and benzol, acetylene heated with many hydrocarbons combines with them freely; formene, water, carbonic dioxide, heated with hydrocarbons, either do not combine with them, or do so at a very high temperature only. The reason of this difference appears to be that the formation of ethylene and of acetylene is attended by a very slight evolution or even by an absorption of heat; the compounds when formed retain much energy, resembling in some degree simple bodies, and in their combination with other bodies positive work is performed with disengagement of heat; the formation of formene, water, carbonic dioxide, and ammonia is effected with great disengagement of heat, and their combination with hydrocarbons with elimination of hydrogen, if occurring at all, will be accomplished with difficulty from the negative work of the direct affinities, and the

absorption of heat attending the elimination of hydrogen; therefore in these cases it is necessary to call in the aid of bodies possessed of powerful affinities to supplement the negative work, and to perform the reactions by some indirect methods.—(*Bull. Soc. Chim. Paris*, 1867, 122.)

MISCELLANEOUS.

Scientific Lecturing pays well in America. Professor Agassiz lately delivered a course of lectures under the auspices of the New York Association for the Advancement of Science on the Natural History of Brazil, for which he demanded and was paid 500 dollars each, or 3000 dollars for the course of six lectures. Taking the time he devoted to each lecture—that is to say, an average of one hour and forty minutes—it thus appears that he received five dollars a minute for every minute he spoke. It appears, however, that the association which engaged his services did not lose.—*Pall Mall Gazette.*

Extraction of Indium from the Products of the Roasting of Blende.—The flue dust which condenses in the chimneys of the zinc works of Gosler contain indium. The author has operated on 100 kilogrammes of this dust, which contains about one part of oxide of indium in 1000. To extract this metal, boil the deposit for half an hour with hydrochloric acid, and digest the clear liquid with pieces of zinc for six hours at the ordinary temperature. There is then deposited a black metallic powder, which is washed with water, and which contains copper, arsenic, cadmium, thallium, and indium. By boiling this with a concentrated solution of oxalic acid, a solution of cadmium, thallium, and indium is obtained; the latter is precipitated by ammonia, and the precipitate is then boiled with ammonia and afterwards with water, until the washings contain no more thallium. The oxide of indium is then almost pure, and only contains traces of iron, from which it may be freed by Dr. Winckler's method given in the Chemical News, vol. xiv. p. 157.—*M. Boettger*, in the *Journal für praktische Chemie*, t. xcviii. p. 26, No. 9.

Determination of Iodine by Means of Chloride of Silver.—To determine the iodine contained in organic hydriodates, M. Kraut digests the solution for several minutes with a known quantity of recently precipitated chloride of silver; the increase of the weight of the chloride of silver is in proportion to the amount of iodine. This method has the advantage of not altering the substance beyond the removal of its iodine, which is replaced by chlorine. The process is very useful in many cases.—*Zeitschrift für analytische Chemie*, iv. 167.

Meetings for the Week.

Monday, May 6.

Royal Institution, 2 p.m. General Monthly Meeting.

Tuesday, May 7.

Royal Institution, 3 p.m. Professor Blackie "*On Plato.*"

Pathological Society, 8 p.m.

Geologists' Association, 8 p.m.

Wednesday, May 8.

Geological Society, 8 p.m. Dr. J. W. Dawson "*On a New Specimen of Eozoon*," with an introduction by Sir W. E. Logan. W. Whitaker, Esq., "*On Subaërial Denudation, and on Cliffs and Escarpments of the Chalk and Tertiaries.*"

Society of Arts, 8 p.m.

Microscopical Society, 8 p.m.

Thursday, May 9.

Royal Institution, 3 p.m. Professor Huxley "*On Ethnology.*"

NOTES AND QUERIES.

Transformation of Naphthalin into Benzoic Acid.—Sir,—Can you inform me where I can obtain a formula for this process, mentioned in your number, 385, page 197, in Notes on the Paris Exhibition?—Sydney Hall. Swansea.

Nitro-benzol.—Sir,—Can you tell me how nitro-benzol can be obtained colourless and free from the tarry smell which usually accompanies it?—A Manufacturer.

Depositing Platinum Electrolytically.—Sir,—Will any of your correspondents tell me what is the best solution and battery power to be used for depositing a coherent film of platinum on brass? I should like it to be strong enough to resist liquid acids, but if this is impracticable, a resistance to acid vapours will suffice.

Chinese Blue.—Sir,—A friend of mine is desirous of obtaining a good receipt for making Chinese blue. He is a large consumer, and wishes to manufacture for himself and another house. He has made it, but not satisfactory in comparison with London manufacturers. He would of course pay handsomely for it. Would it be possible to obtain this? and through what channel?—R. H. W. Manchester.

Purified Shellac.—Sir,—In reference to the suggestion in your last number, I am the inventor of a new method of bleaching and purifying shellac, not by chlorine or its homologues, or by any injurious agent; it is in a state of solution in methylated spirits, and is applicable to gilt work, &c., not injuring anything it is applied to. To any one with a small capital, or in the above way of business, my services would be of value. I am not a thorough chemist, but possess a slight knowledge sufficient for the above. I cannot afford to advertise much, and think this would come under the head "Notes and Queries."—E. M. Nash.

Caramel Colours.—Sir,—Can any of your numerous readers tell me the best way to make these? I am a vinegar manufacturer, and use a considerable quantity for giving a dark colour to the vinegar. The manufacture is kept a profound secret by those few houses who make a speciality of it. I have made several attempts, but have hitherto been unsuccessful.—E. A. Glasgow.

ANSWERS TO CORRESPONDENTS.

*** All *Editorial Communications* are to be addressed to the Editor, and *Advertisements* and *Business Communications* to the Publisher, at the Office, 1, Wine Office Court, Fleet Street, London, E.C. *Private* letters for the Editor must be so marked.

*** In publishing letters from our Correspondents we do not thereby adopt the views of the writers. Our intention to give both sides of a question will frequently oblige us to publish opinions with which we do not agree.

F. W.—Declined with thanks. Your discovery possesses no novelty.

J. Glen and *A Constant Subscriber.*—In our next.

D. H. W.—M. Stas's researches have appeared in the *Proceedings of the Royal Academy of Belgium.* Inquire at Asher's.

G. M. E., Brighton.—The instrument is not yet complete. A full description will appear in the Chemical News as soon as it is in operation.

H. P. Meaden, Haslingden.—A letter is waiting for this gentleman at our office. If he will send his present address, it shall be forwarded to him.

M. Mond's Process for the Recovery of Sulphur from Alkali Waste.—The inventor has drawn our attention to the description of this process given by our Paris correspondent in our number for April 12, p. 181, as not being sufficiently clear. After saying that the process consists in forcing a current of air into the waste in order to oxidise it, and then lixiviating, the description should continue, "The solution is then drawn off, and air again forced into the waste, the mass again lixiviated, and the same treatment repeated a third time. The vats are so arranged that the liquor is allowed to run from one vat into the other in order to obtain it as concentrated as possible. The whole of these operations can be performed in from sixty to seventy-two hours." In the subsequent description, hyposulphite of lime should have been spoken of, instead of hyposulphite of soda. M. Mond says that the process is being successfully employed at many alkali works in England, amongst others at Messrs. Hutchinson and Co.'s, Widnes.

Communications have been received from Pritchard, Burden, and Co.; S. Hall; Rev. B. W. Gibson; T. Davies; P. M. Sargeant; J. Pratt; J. Tomlinson; M. Burton; H. Gillman; J. Hargreaves; J. W. Swindells; W. T. Suffolk; W. M. Bywater; Lloyd Smith; George Dutton (with enclosure); H. B. Condy; John Hull; Charles A. Wright; T. B.; Wotherspoon and Co.; G. M. E.; Sir W. Thompson (with enclosure); Geological Society (with enclosure); Dr. H. W.; F. Webb; G. Penney; Dr. S. Muspratt (with enclosure); R. H. W.; Sir H. J. Brownrigg; The Quekett Microscopical Club (with enclosure); J. Glen; A Constant Subscriber; G. A. Keyworth; L. Mond.

Books Received.—"Chemical Notes for the Lecture Room," by D. Wood, F.C.S.; "The Poisons of the Spreading Diseases," by B. W. Richardson, M.A., &c.

THE USE AND ABUSE OF BLACKBALLING.

We feel constrained again to draw attention to certain unprecedented proceedings which have distinguished the last two meetings of the Chemical Society. For some years the laxity of Fellows in exercising their right of blackballing candidates for Fellowship whose claims were clearly inadequate to entitle them to that honour has been a subject of general comment. Owing to the exceptional position held by the editor of this paper as journalist, and at the same time as a Fellow of the Chemical and other learned bodies, a friendly correspondence with many chemists in all parts of the country has been carried on at one time or another on matters connected with their Society. We are thus necessarily in a favourable position for ascertaining the existence of any grievance among the members.

The Council, as announced by the President at the anniversary meeting, finding that a wide-spread feeling of dissatisfaction existed at the undue facility with which anybody could join the Society, and that this privilege had been on more than one occasion seriously perverted for trade purposes, have lately had under discussion the best method of diminishing this abuse, and restoring to the title F.C.S. its former honourable distinction.

The subject of raising the qualification or restricting the admissions is beset with many difficulties; but those of our readers who are Fellows of the Chemical Society may rest assured that this question is receiving, and will continue to receive, the very serious attention of the Council. When the time comes for a proposal to alter the by-laws at a general meeting, we are convinced that the explanations and the reasons for such alterations, which will then be brought forward, will be adopted by a large majority.

The fact, then, is, that candidates have been admitted too freely. Country members complain that their brother members in London never exercise the right to blackball a candidate. It seems strange that attention should now have to be called to the fact that this undoubted right, so long in abeyance, is now apparently abused in a manner so reckless and suicidal as to seriously imperil the interests of the Society.

A few weeks ago we alluded to the abortive attempt on the part of a few junior members to rearrange the list of Council and officers. Failing signally in that endeavour, it would seem as if they were now attempting, by a concerted plan of action, to assume the governing power in the Society by blackballing candidates irrespective of scientific position or attainments. Thus, party interests are made secondary to scientific progress, and the healthy existence of the Society is imperilled for the gratification of private pique.

Of the five hundred Fellows of which the Society consists, seldom more than forty regularly attend the meetings, and of these the majority have hitherto abstained from balloting. According to the by-laws, "when less than three-fourths of the Fellows who vote are in favour of the candidate, he shall not be elected a Fellow;" supposing then that forty-seven voters are present, it will be seen that a dozen disaffected members are able practically to control the ballot box. Fellows should remember that the possession of a legal right to blackball a candidate, does not imply a moral right to abuse this privilege. They hold this in trust, to be exercised honestly for the good of the Society. In the "obligation" which each Fellow signs on his admission, he engages "to promote the interests and welfare of the Chemical Society," and he is not justified in recording an adverse vote simply to gratify the pitiful ambition of a small party, or to exercise a paltry spite against those who have won the confidence and support of the majority of members.

Between those elected and those rejected at the last meeting we wish to make no invidious comparisons. Few will dispute the qualifications of the fortunate candidates, but those rejected, from their position and scientific acquirements, may be fairly said to possess a very good claim to the coveted honour. In the absence of definite acquaintance with the qualifications of any candidate, the Fellows are, in a certain sense, morally obliged to vote for any one who has so excellent an array of recommenders from personal knowledge as could be seen on the certificates of the gentlemen who had to suffer, for no fault of their own, the indignity of rejection.

Before it is too late, we wish to appeal to the good sense of those who think themselves aggrieved. If they conscientiously object to a candidate, no one would ask them to violate their convictions by voting in his favour; but if they have any grievance, or wish to propose any alteration in the method of conducting business, let them adopt a straightforward course. We can promise them a patient and attentive consideration of any measure they may wish to introduce; but it is unbearable that ten or a dozen young men should, by devious strategy, attempt to overrule the wishes of the Council and of the great body of members.

Apart from the bad policy of making themselves personally obnoxious to the leading men of their science, the malcontents should consider that they are powerless permanently to control the elections; they could but snatch a momentary triumph, for immediately after the necesssary alteration of the by-laws the rejected candidates, if they still cared for the honour, would come forward with a fair prospect of election. A slight modification in the by-laws for the election of Fellows, which would certainly be approved at a general meeting if brought forward by the Council, would take from any clique a power which may be so unwisely wielded. The problem to be solved is how to guard against the admission of unfit persons into the Society, and at the same time to prevent voting by ballot becoming an organ for the gratification of private pique. In several ways the necessary alteration could be made, but we hope such a step will not be forced upon the Council.

London University.—Professor Williamson, Ph.D., F.R.S., and H. Debus, Esq., Ph.D., F.R.S., have been re-elected Examiners in Chemistry for the University of London. The salary of each office is 175*l.* per annum.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On the Classification of Native Silicates, by* William Odling, *M.B., F.R.S.*

(*Continued from page* 165.)

Again, the function of aluminium or alumina, in some particular silicate, is occasionally open to considerable question. Aluminium salts, it is well known, are derivable from acids, either by the substitution of an atom of aluminium, Al‴, for three atoms of hydrogen, as in ordinary alum $Al'''KS_2O_8.6Aq$; or by the substitution of an atom of aluminyl $(AlO)'$ for one atom of hydrogen, as in ordinary acetate of aluminium (the soluble diacetate of Crum) $C_2(AlO)'H_3O_2.2Aq$, or $Al'''O''(C_2H_3O_2)'.2Aq$. In the majority of aluminium-silicates, the aluminium would seem to play the same part that it does in ordinary alum, while in others it may not improbably function as aluminyl. Thus by viewing cyanite and topaz as aluminylic silicates, their anomalous formula $Al_2O_3.SiO_2$, would become reducible to the metasilicate type, and appear as

$$(AlO)_2O.SiO_2, \text{ or } (AlO)_2SiO_3;$$

while euclase would become an orthosilicate, thus—

$$(AlO)_2G_3O_4.Si_2O_4, \text{ or } (AlO)_2H_2G_2O_4.Si_2O_4.$$

But aluminium is not only capable of acting in two distinct fashions as a base, but it can also play the part of an anhydride corresponding to silica. Spinelle, $MgO.Al_2O_3$, and augite, $MgO.SiO_2$, for instance, may be regarded as analogous, though heteromorphous compounds; and it has been contended by Bonsdorff and others, with considerable show of reason, that in the aluminous augites and hornblendes, the alumina does not act as a base to the silica, but is substituted for a variable amount of the silica isomorphously. Similar remarks apply to boric oxide, B_2O_3, which, in some silicates, as axinite, appears to replace a variable but small proportion of basic alumina or aluminyl, while in others, it obviously fulfils the functions of an anhydride, as in datolite and botryolite.

$$Ca''_2H_2\begin{Bmatrix}B_2O_4\\Si_2O_6\end{Bmatrix} \qquad Ca''_2H_2\begin{Bmatrix}B_2H_2O_5\\Si_2O_6\end{Bmatrix}$$

In the great majority of well-defined aluminous double silicates, the ratio of monad and diad to triad or pseudo-triad metal is either the spinelle ratio

$$M''O \text{ to } Al_2O_3,$$

or else the cryolite ratio

$$M''_2O_3 \text{ to } Al_2O_3,$$

as exemplified below:—

Spinelle Silicates.

Ortho.	$CaAl_2O_4.Si_2O_4$	Anorthite. Wernerite.
1/1	$CaAl_2O_4.Si_2O_4.2Aq$	Thomsonite.
	$CaAl_2O_4.Si_2O_4.4Aq$	Gismondine.
Para.	$CaAl_2O_4.Si_3O_6$	Labradore.
2/3	$Na_2Al_2O_4.Si_3O_6.2Aq$	Mesotype.
	$CaAl_2O_4.Si_3O_6.3Aq$	Scolezite. Mesolite.
	$CaAl_2O_4.Si_3O_6.4Aq$	Zeagonite.
Meta.	$K_2Al_2O_4.Si_4O_8$	Leucite.
1/2	$Na_2Al_2O_4.Si_4O_8.2Aq$	Analcime.
	$CaAl_2O_4.Si_4O_8.3Aq$	Leonhardite.
	$CaAl_2O_4.Si_4O_8.4Aq$	Laumonite.
	$Na_2Al_2O_4.Si_4O_8.5Aq$	Phillipsite.
	$CaAl_2O_4.Si_4O_8.6Aq$	Chabasite.
Sesqui.	$K_2Al_2O_4.Si_6O_{12}$	Felspar. Orthoclase.
1/3	$Na_2Al_2O_4.Si_6O_{12}$	Albite.
	$CaAl_2O_4.Si_6O_{12}.3Aq$	Parastilbite.
	$CaAl_2O_4.Si_6O_{12}.5Aq$	Epistilbite. Heulandite.
	$CaAl_2O_4.Si_6O_{12}.6Aq$	Stilbite. Desmine.

* Dr Odling has kindly given us permission to publish occasional chapters from the forthcoming second part of his "Manual of Chemistry."—Ed. C. N.

Cryolite Silicates.

Basic.	$Ca_3Al_2O_6.Si_2O_4$	Gehlenite.
3/2	$Fe_3Al_2O_6.Si_2O_4$	Aphrosiderite.
	$G_3Al_2O_6.Si_2O_4$	Euclase.
Ortho.	$Ca_3Al_2O_6.Si_3O_6$	Garnet. Idocrase.
1/1	$Mg_3Al_2O_6.Si_3O_6$	Allanite. Orthite.
	$(NaCa)_3Al_2O_6.Si_3O_6$	Sarcolite.
	$(HCa)_3Al_2O_6.Si_3O_6$	Prehnite.
Para.	$Mg_3Al_2O_6.Si_4O_8$	Mica?
Meta.	$G_3Al_2O_6.Si_6O_{12}$	Beryl.

Other ratios are, however, occasionally met with, as in the following examples, and particularly the mixed ratio $MO + M_3O_3$ to $2Al_2O_3$, and the double ratio $2M_3O_3$ to Al_2O_3:—

Para.	$K_2Al_6O_{10}.Si_6O_{12}$	Potash-mica.
,,	$Mg_4Al_4O_{10}.Si_6O_{12}$	Magnesia-micas.
,,	$K_2Mg_3Al_4O_{10}.Si_6O_{12}$	
	$(LiK)_2Mg_3Al_4O_{10}.Si_6O_{12}$	Lepidolite.
,,	$Ca_4(AlB)_4O_{10}.Si_6O_{12}$	Axinite.
,,	$Ca_6Al_2O_9.Si_6O_{12}$	Humboldtite.
Meta.	$H_{12}Al_2O_9.Si_9O_{18}$	Cimolite.
Ortho.	$Ca_6Al_8O_{18}.Si_9O_{18}$	Epidote.
Meta.	$Li_6Al_8O_{15}.Si_{15}O_{30}$	Spodumene Triphane.
Anhy.	$(LiNa)_6Al_8O_{15}.Si_{30}O_{60}$	Petalite.

(δ) Among so-called hydrated silicates, the determination of the function of the constituent hydrogen is often a matter of considerable difficulty. It is clear that this hydrogen sometimes exists in the form of water of constitution or crystallisation added to the proper silicate molecule, whereas in others it exists as basic hydrogen, forming an integral part of the silicate molecule; but the means for determining the particular cases in which it exists in the one state or the other, or in both states simultaneously, are usually very imperfect, and sometimes entirely wanting. Dioptase, for example, may either be considered as an orthosilicate of hydrogen and copper, $H_2Cu''SiO_4$, or else as a hydrated metasilicate of copper, $Cu''SiO_3.Aq$, and so in many other instances.

The isomorphism of basic hydrogen with certain basic metals, and more particularly with magnesium, though scarcely established beyond question, is warranted by many facts relating to hydrated silicates. Thus, in several definite silicates, while the proportion of constituent hydrogen is very variable in different specimens, yet, reckoning this hydrogen as basic water, the ratio of the oxygen of the united bases to the oxygen of the silica is almost constant, and identical with the ratio of some typical compound. A variety of talc, for instance, is sometimes represented by the anomalous formula—$Mg_6O_6.Si_7O_{14}.Aq$; but, bearing in mind the temperature required to render such talc anhydrous, it can scarcely be doubted that its proper formula is really

$$H_2Mg_6O_7.Si_7O_{14};$$

or, seeing that the proportion of hydrogen is variable in different specimens, $(HMg)O.SiO_2$.

Prehnite, again, is usually expressed by the formula $Ca_2Al_2O_3.Si_6O_{12}.Aq$; but, independently of the exceptional ratio of lime to alumina, and of base to silica shown by this formula, in reality the proportion of hydrogen or water in different specimens of prehnite varies very considerably. But reckoning the hydrogen or water as basic, the oxygen of the united bases is to the oxygen of the silica exactly in the ratio 1/1, and the oxygen of the triad to that of the joint diad and monad bases approximately in the ratio 1/1 also. Similarly, in the different varieties of mesotype, there often exists,

in addition to the water formulated as water of crystallisation, a variable small excess of water which contributes to furnish the full complement of base appertaining to the particular silicate.

(ε) It is well known that the production of crystals, either by way of fusion or solution, is much affected by the presence of different impurities, dissolved or suspended in the crystallising liquids; and that, as a rule, the finest crystals are obtained from impure liquids, and carry down with them a certain proportion of impurity. Now, native silicates have all the character of crystals formed from impure liquids, and undoubtedly do contain, in many instances, a greater or less amount of accidental impurity. Chabasite, for example, frequently contains an excess of uncombined silica, with which, indeed, it is isomorphous; while some crystals of augite are said to contain a small proportion of garnet; and similarly in several other cases. Moreover, it is not improbable that certain definite silicates may contain variable proportions of other silicates—that a spinelle-silicate, for instance, may contain some cryolite-silicate, and a metasilicate some sesqui-silicate — in a state of perfect homogeneity, and without affecting their special crystalline forms; just as the heteromorphous alloys, Sb_2Zn_3 and Sb_2Zn_2, may each contain a not inconsiderable proportion of the other, without prejudice to the distinctive character of their respective crystalline forms. Altogether, while the analysis of artificial compounds is habitually preceded by their elaborate purification, that of native silicates is performed at once upon compounds never free from more or less accidental impurity, which, occurring in an otherwise definite silicate, may interfere very seriously with the right interpretation of the results of its analysis.

(ζ) Lastly, considering the number of operations to be performed, and of precautions to be taken, in order to obtain an accurate estimation of some one constituent only of an ordinary silicate—such as the alumina, or magnesia, or soda—it is evident that the difficulty and complexity of the processes employed in the complete analysis of most native silicates must be considered as detracting somewhat from the absolute certainty of even the percentage results arrived at. To this consideration may be added the probability, insisted upon by Laurent, that the few tenths or even hundredths of water contained in many silicates, and frequently disregarded both in the statement of results and calculation of formulæ, may sometimes, at any rate, fulfil a very important function in the constitution of the several minerals, and permit the association of their respective formulæ with those of well-recognised typical compounds.

Bearing in mind, then, the many circumstances interfering with the accurate determination of their molecular composition, it would appear that the actual types of native silicates are much fewer and simpler than is generally supposed; and, that in the great majority of instances, where the chemical formula of a mineralogically well-defined silicate is deduced from the analyses of a considerable number of different specimens, the ratio of the oxygen of the alumina to the oxygen of the other bases will prove to be either the spinelle- or the cryolite-ratio, or occasionally that of some closely related compound; while the ratio of the oxygen of the silica to the oxygen of the united bases will prove to be that of an ortho-, para-, meta-, or sesqui-silicate; and that in the majority of instances, where these ratios are seemingly departed from to some extent, the departure will be found really due to a partial substitution of alumina for some stronger base on the one hand, or for some silica on the other; or to a non-recognition of some constituent water; or the presence of some accidental impurity or intermixture. Altogether it is evident that a considerable latitude must for the present be permitted in the assignment of formulæ to complex native silicates, and especially to those of which but a few specimens have been submitted to careful analysis.

On the Purification of Chloride of Ammonium by Volatilising it in a Vacuum, by Prof. J. S. Stas.

The following is the method employed for the volatilisation of sal ammoniac in a vacuum:—

Forty grammes of chloride of ammonium obtained by the direct combination of hydrochloric acid with the ammonia produced by the reduction of nitrite of potassium, were introduced into a glass tube, ninety-five centimetres long and three centimetres in diameter, closed at one end and open at the other. The chloride, first well dried, being placed at the closed end, I placed the tube in a horizontal position on the metallic support of a gas jet; I put the open end against another open tube of the same diameter, and placed over the junction a glass tube of ten centimetres diameter, which I fixed with a cement of gum lac, letting some of the cement run between the tube and the two juxtaposed portions. To the second tube there was joined a T-shaped tube, whose very short, almost capillary branch went to the branch of a steel tap in which I luted it hermetically with a resinous cement. The vertical branch of the T tube plunged into a test-tube containing mercury. Into the other branch of the tap I cemented a capillary tube in communication with a pneumatic machine capable of making a vacuum in the apparatus of 0·0005 m. To prevent the sal ammoniac, which, in a vacuum, condenses as an impalpable powder, from penetrating into the almost capillary tube and blocking it up, I filled the large tube, to which the T tube was joined, with a brush of fine platinum wires, preceded by a large quantity of calcined and still warm asbestos. Before commencing the sublimation of the sal ammoniac, I made sure that the apparatus kept a vacuum for twenty-four hours. I then proceeded to the volatilisation. For this purpose I heated directly in a gas flame the part of the tube containing the sal ammoniac, *taking the precaution of keeping the temperature as low as possible.* During the sublimation the mercury continually oscillated in the vertical branch of the T tube, and the chloride condensed partly as dust and partly as a thick colourless ring. After the tube was cool enough for all tension to be removed from the sal ammoniac, the mercury rose in the tube to the same level as before the operation—a proof that no gas was formed during the sublimation but what was condensed afterwards. I made a second and then a third volatilisation of the same sal ammoniac. During the two latter volatilisations I took care to keep the air-pump continually at work, so as to carry off any gas that might be produced.

After the tube was quite cold, the sal ammoniac, which was sublimed in a compact ring, detached itself noisily from the tube, becoming at the same time opaque instead of transparent and highly refracting, as it was whilst hot.

I determined separately, and as they came from the tube, the proportional ratio of the sal ammoniac in a compact mass and in impalpable dust. Both contained traces of sodium, which, however, could only be appre-

ciated by spectral analysis; they probably acquired this metal from the ordinary white glass tube, in which the triple volatilisation was performed.

TECHNICAL CHEMISTRY.

On the Waste of Materials in the Alkali Manufacture, by JAMES HARGREAVES.*

(*Concluded from page* 220.)

5. **By non-decomposition or imperfect decomposition of sulphate of soda.**—The loss from this cause varies considerably in different manufactories. In some the average quantity of sulphate, or its equivalent in sulphate with sulphide, &c., is as 5 of sulphate to every 100 parts of available alkali, which is equal to a loss of 2·19 parts for every 100 parts of sulphate made available. In others (where the works are too small to afford, or the managers are too "economical" to employ, scientific supervision) the loss not unfrequently averages 24 parts of sulphate to every 100 parts of available alkali, by which 9·22 parts of the sulphate remain unavailed for conversion into carbonate for every 100 utilised. The loss from this cause generally varies between these proportions, more frequently exceeding the latter than going below the former.

The sulphate may remain unaltered in consequence of deficiency of carbonaceous matter, too low temperature of the furnace, or insufficient or unskilful working; or the decomposition may have only proceeded so far as to produce sulphide of sodium, without reacting on the carbonate of lime used in mixing the charge. This is the result of either a deficient quantity of carbonate of lime or bad working in the furnace.

When the crude soda or "black ash" is exposed to too high a temperature, an allotropic modification of sulphide of sodium is formed. This modified sulphide does not react on the lime present in the charge, but remains unchanged, and the black ash, instead of a grey, is of a dull brick-red colour, and forms a blue solution with water. When chlorine is passed through a solution from this red ash to convert the sulphide into sulphate, there is only a small portion so converted; the rest of the sulphur from the sulphide is precipitated—not being soluble in the alkaline solution—and may be separated by filtration. By this it is obvious that there is no dependence to be placed on the use of chlorine to convert the whole of the sulphide into sulphate, when the black ash is "burnt," and the loss shown by analysis is less than the real loss.

6. **By oxidation of crude soda.**—There are some manufacturers who think nothing of allowing the black ash to be exposed for several days to the weather before being lixiviated. When the weather is dry no harm is done, but in wet weather the balls are moistened, and the sulphide of calcium is rapidly converted into sulphite, hyposulphite, and sulphate of lime, which, reacting on the carbonate of soda, forms the corresponding soda salts, while the lime is converted into carbonate. To avoid this, the black ash must be kept quite dry, and not kept too long a time, but it should have sufficient time to become quite cold.

This action is also frequently continued in the vats, which being filled too full with black ash, a great quantity is exposed to the air in a wet condition. Each vat should not be filled so full but that the whole of the black ash can be covered with water at once, and never allowed to be uncovered till the vat is spent and run off. The vat liquor contains more sulphate in proportion to the available alkali than is contained in the black ash as drawn from the furnace, in consequence of this oxidising action of the atmosphere. The loss of alkali from this cause is seldom less than 0·2 per cent. of the whole; but I have frequently seen black ash in which the parts most exposed to the weather have had more than one-third of the alkali reconverted into sulphate of soda.

7. **By inversion of the furnace reaction.**—When the water used in lixiviating the black ash is too hot, the furnace reaction is inverted, the sulphur combining with the sodium, and the oxygen and carbonic acid with the calcium—

$$NaOCO_2 + CaS = NaS + CaOCO_2.$$

This reaction takes place more rapidly in weak than in strong solutions, and is therefore more apt to occur where the water is run on the weak vat warm, than when it is warmed by steam in each vat separately, raising the temperature a little in each successive vat till it reaches the strongest one.

If the vats are not perfectly cleaned from the waste from former charges every time they are discharged and filled, the waste remaining, and which has been exposed to the atmosphere, becomes partially oxidised, reacts on the soda solution, and forms soda salts of the sulphur acids, and the whole of the soda thus combined is for all practical purposes lost.

8. **By imperfect lixiviation.**—If an insufficient quantity of water is run through the vats, or the water is too cold, or the vats are worked too rapidly, or the black ash is thrown into the vats in too large lumps, or is deficient in porosity, a considerable quantity of alkali is left in the waste, and thrown away with it.

This loss is greatly increased by having too small a space for lixiviating the black ash, which allows too short a time for extracting its soluble constituents, and necessitates the use of hot water, thereby offering the alternatives of sustaining loss by decomposition of carbonate of soda, or by leaving soda in the waste, or needing a great expense to concentrate the liquor; for if hot water is not used a much larger quantity of water is required to extract the alkali, and as the solution contains a smaller proportion of alkali, the use of a larger quantity of fuel is required to concentrate it. These evils are best overcome by having ample vat space.

The waste should not contain more than 0·1 per cent. of alkali, which is equal to about 0·45 per cent. of the whole alkali originally present in the black ash. But it not unfrequently amounts to ten or even fifteen times this amount where there is no proper supervision of the vats and analysis of the waste.

9. **By spilling, leakage, &c.**, in moving material from place to place. This is a mechanical rather than a chemical question, and how to prevent it is too obvious to require comment.

The foregoing shows that, without any alterations in the principle of Le Blanc's process, there is still a large margin for improvement in the details of the soda manufacture.

FOREIGN SCIENCE.

(FROM OUR OWN CORRESPONDENT.)

PARIS, May 8, 1867.

THE learned societies of the Scientific Association of France held their annual public meeting at the Sorbonne, Wed-

nesday, Thursday, and Friday of Easter week. The meetings were not well attended, and the few subjects discussed were not very interesting; the attraction of the Exhibition threw them into the negative pole of sight-seeing or lecturing. The distribution of the prizes took place on Saturday, April 28, at noon. M. Blanchard, Professor of Natural History at the Museum of Natural History, and member of the Academy of Sciences, gave a good summary of the scientific works carried on in 1866—1867. His good nature and lively imagination were actually necessary to conceal or counteract a truly lamentable sterility of subjects. We must say, notwithstanding the rather timid protestation of the Minister of Public Instruction, that the sciences, mathematics, physics, geology, botany, and meteorology have lost in France much of their ground; our mathematicians, physicists, and naturalists have let themselves be outstripped by foreign *savants* on the field of pure science. The Prussian needle-gun and the Enfield rifle have taken the palm out of our hands; they have, we may say, silenced the fire of our rifles.

This is a sad statement, but, alas! too true. The Congress that we have above mentioned was only a gloomy shadow compared with a meeting of the British Association for the Advancement of Science.

Apropos of the ozone-generating machine experimented upon by Mr. Beanes at the last *soirée* of the Royal Society of London, let us humbly call to mind that we were the first to make known the nature and application of this mysterious agent. In 1845, on the first news of the curious observations of M. Schönbein, we proceeded to Basle, and visited the celebrated chemist and professor. He condescended to repeat before us his numerous experiments, and we wrote to the *Epoque* a letter inserted on December 31. The following very important passage occurs:—"It is necessary to return immediately to the ideas of Ampère, and consider the atoms of bodies as having two states—first, with the essential primitive electricity or in a nascent state; second, with their electricity more or less disseminated, or their atmosphere of electricity in a neutral state. The ozone of M. Schönbein is, in our eyes, only a molecule of oxygen in a nascent state, with only negative electricity in its atmosphere. I am, I think, able to rigorously prove and account for the wonderful properties of this agent that we cannot lay hold of, and of which so much has been said." We ask all the chemists in general of that time, and Dr. Thomas Andrews, of Belfast, in particular, whether at that period any one had so clearly defined the essential nature of ozone, so much talked about, written upon, and discussed without coming to a decided conclusion.

Two years afterwards, when uncertainty yet reigned in all minds, we inserted in the *Nouvelle Revue Encyclopédique* of M. Didot, in the number for July, 1847, the following more explicit lines:—"Sufficient attention has not been yet paid to the important fact that oxygen disengaged by plants is not in a neutral state. We are perfectly convinced that this nascent oxygen, without its positive atmosphere, is the ozone discovered by M. Schönbein, with an odour *sui generis*, and possessing, in the highest degree, all the properties of electro-negative substances. The bleaching of linen stuffs, ivory, wax, &c., in the open air, on grass, the formation of nitric acid and saltpetre, also many other phenomena, are only caused by the powerful action of oxygen in a nascent state, or with its negative electricity developed." From 1845 to 1867, thousands of contradictory opinions have been written on the subject of ozone, to return again to the idea that we so clearly pointed out. We have so often pleaded the cause and defended the interests of others, that we must be pardoned for establishing, once for all, and very humbly, our own claims.

The Society for the Encouragement of National Industry has decided that, during the whole time of the Exhibition, it will hold weekly meetings, not on Wednesdays, as on that day too many members of the Council will be elsewhere engaged, but on Friday, when one is in general more free from domestic or social engagements. The first of these meetings took place on May 3, under the presidency of M. Dumas, and the aspect of the hall, the tables covered with crystal and glass, gas burners, objects in aluminium, &c., show at once a successful departure from the habits of the Society. The correspondence was, as usual, opened by the two secretaries, but it contained nothing interesting. M. Tessié de Mothay, in his name and that of M. Maréchal, of Metz, read a description of the processes of phototype which have led them to the definitive solution of the great problem of the indefinite reproduction, with thick and indelible inks, of photographic images. M. Tessié regarded as antiquated the anterior essays with regard to M. Davanne, of whom we have already spoken. He need not then speak of the photographic processes of MM. Niépce de St. Victor, Lerebours, Lemercier, and Barreswill, long since practised by the eminent photographer, M. Lemercier. Meanwhile, M. Barreswill thought proper to call to mind this first solution, and even thought that he was able to add that he had given results almost identical with those of the new process. We venture to affirm the contrary, and we are sure we shall not be contradicted on this point by M. Lemercier, who is very glad to substitute the new process for his own, the success of which was uncertain. The employment of so large a quantity of ether rendered difficult and unhealthy the process, which had already given way to the incomplete method of M. Poitevin.

M. Dumas then gave the *parole* to M. Paul Bérard, who directs, with M. Paul Audouin, the Laboratory of Essay for the Illuminating Power of Gas, established in the Rue du Faubourg Poissonnière for the Municipal Administration of Paris, under the head direction of MM. Dumas and Regnault. The young chemist resumed, and confirmed by many experiments, results obtained, having a double view—1. Two flames of equal intensity being given, one produced by a carcel lamp burning under fixed conditions, the other by a gas burner, burning as much as possible under the same conditions, to determine the respective consumptions of oil and gas, in a given time, for each of the apparatus; 2. To study different burners, and the best conditions for the combustion of the gas.

The first problem was completely resolved by a series of photometric apparatus, very well constructed by M. Deleuil, and which comprise a carcel lamp burning at the normal rate of oil, a Foucault photometer with starched glass plates, and a telescope and movable plates, a standard burner and an argand one with 30 holes, and an automatic balance indicating by a scale, with the precision of 1 centigr. for a charge of 3 kilos., the quantity burned by a carcel lamp. M. Audouin said nothing of the photometric method; he did not even mention the name of M. Deleuil, but he enumerated very rapidly the conclusions of the experiments on burners. Let us mention them, as they are truly well defined. With *bat's-wing burners* the maximum of illuminating power corresponds to a slit $\frac{7}{10}$ths of a millimetre wide. The same quantity of gas can give, when it burns in a good burner, four times the light given by a bad one. The increase of illuminating power corresponds to a very rapid diminution of pressure, and consequently to the diminution of the velocity of flow; in other terms, with equal consumptions of gas of a constant composition, the greatest illuminating power corresponds to the lowest pressures, the maximum corresponding to a pressure of 2 to 3 millimetres. The proportion between the diameter of the nipple and the expenditure, keeping the same width of slit, $\frac{7}{10}$ths of a millimetre, has next to be determined. The gas flows with the same velocity or under the same given pressure, always with the same illuminating power, whatever be the bat's-wing in which it burns. For very different

intensities the dimensions of the flame vary very little, its height being sensibly constant and terminated by a right line. *Other burners than bat's-wings.* Bougie burner, a nipple with a hole in the centre. For the same height of flame, the illuminating power always coincides with weak pressures and a hole of $\frac{7}{10}$ths of a millimetre; it increases almost indefinitely with the height. The great expenditures of gas are more advantageous than the weak ones. Manchester burner, a nipple pierced with two holes. When the diameters of the holes are very small, two bougie burners give a light equal to that of a Manchester burner, which they can form by their union. But the superiority of the Manchester burner over the two bougie burners becomes more and more considerable according as the holes increase in diameter. The maximum lighting power corresponds always to the minimum pressure, and to a diameter of $\frac{7}{10}$ths of a millimetre. *Burners with a double current of air.* The argand burner of 30 holes, $\frac{7}{10}$ths of a millimetre, proved the most advantageous of all, and it is much to be regretted that it was not compared with the Monier burner, which is much more economical again. The lighting power increases indefinitely with the expenditure; the height of the chimney should not exceed 20 centimetres. The quantity of air burned by a burner is not proportional to the consumption of gas; all the burners do not require the same amount of air in order to give the maximum of lighting power. The introduction into common gas of 6 or 7 per cent. of air diminishes its lighting power by a half. 20 parts of air mixed with 80 parts of gas gives no light.

The standard carcel lamp consumes 42 grammes of oil per hour. According to the treaty between the town of Paris and the General Gas Company, 25 litres or $27\frac{1}{2}$ litres of gas burned in a standard burner under a pressure of two or three millimetres should furnish a flame equal in intensity to that of a carcel lamp burning during the same time 10 grammes of purified colza oil.

M. Debray then resumed the history of the preparation, properties, and uses of aluminium discovered by M. Wöhler, and brought into use by M. Henri Sainte-Claire Deville. The principal progresses made in this industry are—Utilisation of bauxite, a clay very common in the South of France, composed nearly exclusively of alumina and sesquioxide of iron; to this is due the purity of the aluminium of commerce. The employment as flux of salt and cryolite (double fluorine of aluminium and sodium, very abundant in Greenland). This metal is used for optical instruments, and many other objects of jewellery, &c., and even for culinary purposes. Aluminium bronze, composed of copper 90 to 95, aluminium 5 to 10, is its principal use. M. Debray stated as extraordinary facts that this bronze, containing 95 per cent. of copper, was very little attacked by acids; also that chlorine was a deleterious gas, and sodium poisonous, but that chloride of sodium (table salt) was innocuous!

When M. Debray sat down, M. Dumas rose and indicated in a few words the aim of these weekly meetings. What characterises, he said, the Exhibition of 1867 is the enormous progress made in the application of the sciences to industry and fine arts; everywhere in these immense galleries we see the facts and theories of pure science become materialised into practical applications of great value. Is it not very natural, then, that the Society of Encouragement should become the revealer and appreciator of the successes obtained in what may be called its special department?

We are surprised that the illustrious President does not try some other thing than a reduced copy of our own programme in the conferences of the Exhibition 1867. He attempts to perform far from the galleries, in a very confined space, in presence of a very limited auditory, what we aspire to do in the midst of the Champ de Mars, in a great amphitheatre holding 500 auditors. How does it happen that the Commission of three members, the triumvirate, Dumas, Michel Chevalier, and Perdonnet, charged by the Imperial Commission with its organisation and direction, have not signified to us, by the intermediation of M. Perdonnet, their intentions issued as follows?—1. That the entries shall be gratuitous. 2. That none of the lectures shall be paid. 3. That no exhibitor shall be admitted, either by himself or by a third party, to exhibit or make known the progress he has accomplished. Is it not tyrannically unjust to make gratuitous a lecture-hall, constructed according to a very severe specification entailing an expense of 50,000 to 60,000 fr.? Is it not barbarous to prevent 100 or 200 fr. from being taken from the money received at the doors and given to the *savant* who may have succeeded in interesting a vast auditory, and initiated them agreeably and usefully into the nature and advantages of some novel branch of industry? St. Paul characterised this barbarism in remarkable terms in his Epistle to the Corinthians, when he told us not to muzzle the ox while eating.

Lastly, it is astounding that what is permitted, honourably, legally, and praiseworthily, under the patronage of the illustrious President of the Council of the Society of Encouragement, could at once become illicit and blamable in the eyes of the Imperial Commission, of which he forms part, even of the *triumvirate*. The letter of M. Perdonnet we keep with great care. The triumvirate is totally ignorant of the fact that the lecture-hall was mounted (it is very nearly finished) at private expense on the same terms as the other establishments of the Champ de Mars Park. A lecture-hall on the subjects of objects exhibited seems to us an indispensable adjunct; yet the Commission did not think it worth their while to build one; they gave the concession of ground to the celebrated photographer, M. Pierre Petit (who had already given 2800*l.* for the site for his pagoda), on condition that he would build a lecture-hall and furnish lectures, the profits of course to be his own. Not so. Right about face with the Commission. The lecture-hall being done, and the expense paid for, M. Petit is told that all his labour in that direction is in vain. The Commission should, at least, reimburse the sum he laid out in bricks and mortar to please the Imperial Commission. Do they want to rob him also? Every establishment for public amusement is there opened on the adjoining grounds, and they place *what price they like* for entrance; but intellectual and practical information, the food of the mind, seems to find no favour with the triumvirate. F. Moigno.

PARIS EXHIBITION OF 1867.

(From our Special Correspondent.)

Long ago the researches of Messrs. Deville, Lechatelier and Kessler proved that fluosilicic acid, if it could be produced cheaply, would most advantageously replace sulphuric acid in the great industries of potash and soda. On the one hand, some facts seem to indicate that, under certain conditions, silica, melted with fluoride of lime at the highest temperature of our furnaces, produces fluoride of silicium and silicate of lime; on the other hand, celebrated German and English engineers affirmed that the furnaces for smelting copper with fluoride of calcium disengaged at the furnace mouth fluoride of silicium, which seems to indicate, conformably with the analyses of M. Berthier, that carbon played a great part in the production of fluoride of silicium by the dry way. Starting from these principles, M. Tessié de Mothay caused to be melted in a closed crucible a mixture of two equivalents of silica, three equivalents of fluoride of calcium, and four equivalents of carbon; and he proved that at the temperature of melting iron a great quantity of fluoride of silicium was evolved. The slag resulting from the calcination, when analysed, showed that the fluoride of calcium had lost 52 per cent. of its fluorine; and direct observation proved

that the fluoride of silicium produced was always accompanied by carbonic oxide gas. Convinced by these preliminary experiments of the possibility of the industrial production of fluoride of silicium, M. Tessié de Mothay made, along with M. Ede Kescher, of Sarrebruch, in a melting-pot of the works at Ars-sur-Moselle, a first essay at reduction. This was crowned with complete success, and they proceeded immediately to construct furnaces for the production on a great scale—first, of fluoride of silicium and fluosilicic acid; second, of caustic potash and carbonate of potash, extracted by the action of fluosilicic acid from the chloride of potassium of the Stasfurth mines. The quantity of fluosilicic acid obtained in the blast furnace of Grösbleterstroff, near Sarrequemines, is already sufficient to enable them in some months to deliver a ton of potash per diem at a cheap rate to the trade.

This process of fabrication is very efficacious and simple, since, by aid of fluosilicic acid, they collect 68 per cent. of the fluorine contained in the fluoride of lime. It consists in —1. Kneading, as in a brick-making machine, carbon with a mixture of silex, clay, and fluoride of lime, in quantities proportionately equivalent, and the formation, after fusion in the blast furnace, of a bibasic silicate of alumina and lime. 2. Mixing the cakes with the proportion of coke necessary for the fusion. 3. Filling all the furnaces through a double chamber to hinder the passage of the gases by the furnace mouth. 4. To melt the cakes by an intense heat produced by powerful blowers, and to collect the gases in condensers whose surfaces are continually wetted, so that the immediate contact of the water decomposes the fluoride of silicium into hydro-fluosilicic acid.

In Class 51 is exhibited a complete plan of the works and blast furnaces of Grösbleterstroff; and in Class 44 a series of bottles containing fluosilicic acid of 180°, fluosilicate of potash, of soda, and of barytes, caustic potash, and soda, which the fluosilicic acid has separated from their combinations with sulphuric acid.

Chemists, only a few years ago, would have refused to believe that one could procure so easily and certainly, and on so large a scale, a product hitherto confined to the laboratory, but now destined to modify in the most successful manner one of the most important of modern industries.

Paintings on glass required to be transparent must have a thickness of enamel four or five times greater than that of paintings on ceramic paste which are to be viewed by reflection. Hence it follows—1. That the designs made to be transferred to glass cannot be printed from ordinarily engraved copper plates, since, after baking, it would not have the necessary thickness and opacity; 2. That the organic matters serving as a vehicle for the vitreous flux to make the impressions must be increased in a quantity proportional to the amount of the enamels they are to contain.

In order to resolve the problem of impression by means of applied drawings of enamelled pictures vitrefiable on glass, it was necessary to have recourse to the employment of deeply engraved plates, similar to those for paper-hangings and stuffs, and organic inks containing the enamels in a state of combination.

But all the vehicles hitherto employed for printing enamels, porcelain, and earthenware, when mixed with colouring fluxes in sufficient proportion to permit of the impression, cause on the glass, during the baking, the deformation of the designs, and, in numerous places, non-adherence to the surfaces they cover. The same effects of deformation and non-adherence are equally produced with inks composed solely of resinous siccatives, essences, bitumens, resins, and other analogous vehicles.

MM. Tessié de Mothay and Maréchal have happily proved that the organic inks favour, on the contrary, the union of the vitreous flux with the sheets of glass; in fact, the solvent of the colouring matters used in painting on glass is in general silicate of potash and lead, or a silico-borate of the same bases. This combination, rendered plastic by the addition of more or less resin dissolved in the turpentine, is a perfect ink, which, printed in a thick layer and transferred to glass, is burnt and vitrefied without deformation or air-bubbles. Thanks to it, it is possible to employ, for the reproduction of ornamental or plain prints, the rollers, with deeply cut lines, which serve at Mulhouse for the printing of stuffs. Worked by steam power, these rollers produce in an hour more than 250 skilful designers could do in a day. Many thousands of plain patterns and mosaics of stained glass produced by this process already adorn our churches, and the low price at which they are produced and sold tends every day to multiply the number.

The same investigators have also discovered a new method applicable to the production of photographic images of all sorts on glass, enamel, lava, porcelain, earthenware, &c. It comprehends a series of ten operations, which we will summarily describe in their order:—1. Four parts of caoutchouc are dissolved in a hundred parts of benzol. To this solution is added one part of normal collodion. This compound is poured upon any of the substances on which a vitrefiable portrait is required to be produced. It is then dried, either in the open air or in a stove, until a very coherent coating is formed. 2. On this first coating, thus dried, iodised collodion is poured. This second coating unites intimately with the first, and thus acquires a resistance equal at least to a layer of caoutchouc of the same thickness, a resistance which no ordinary collodion possesses. 3. After having immersed the double coating, thus prepared, in a bath of nitrate of silver, an image is produced on it, either by a camera or by superposition. 4. The latent image thus produced is developed by any of the agents generally used. 5. It is then fixed by successive action of two baths, one containing a solution of an iodocyanide, and the other an alkaline cyanide. 6. The image thus fixed is steeped for some instants in a solution of sulphate of protoxide of iron, pyrogallic acid, or any other substance that will reduce the salts of silver. 7. The image is intensified by the action of pyrogallic acid, gallic acid, formic acid, or sulphate of protoxide of iron, mixed with an acid solution of nitrate of silver. This strengthening requires, on an average, four to six applications, when the image is to be seen by reflection, and twelve to fifteen for those which are to be seen by transparency. During this operation of reinforcement, the images are washed three or four times in alternate baths containing iodo-cyanides and alkaline cyanides, then, immediately afterwards, in sulphate of protoxide of iron, pyrogallic acid, or any other reducers of the salts of silver. The consecutive employment of baths of iodo-cyanides, and of alkaline cyanides, has the effect of completely dissolving the non-adherent silver precipitated over the whole plate in each reinforcing bath, and this without destroying the original image, which alone is intensified. The washings in the reducing bath rendering neutral the metallic surface, increase powerfully the ulterior action of the reinforcing baths. 8. The photographic image, being developed, fixed, and reinforced, is immersed for several hours, either in a bath of chloride or nitrate of platinum, or in alternate baths of chloride of gold and nitrate of platinum, or, again, in baths of chloride of gold. During the steeping, the silver of the image is either partly replaced by platinum, by a mixture of platinum and gold, or by gold alone. The purpose of the different substitutive baths is in order that the colour and nature of the layer of silver of the image may be changed after vitrification. In fact, if it is desired to obtain by the muffle, and by the reactions of silicic or boracic fluxes, images of a greenish black, they are previously immersed in a bath of chloride or nitrate of platinum; if, on the contrary, a black colour be required, they are steeped successively in baths of chloride of gold and nitrate of platinum. When, lastly, gilt images are to be produced, they are plunged into baths containing exclu-

sively salts of gold. 9. The image, on coming from the platinum or gold baths, is washed in a solution of alkaline cyanide or concentrated solution of ammonia; it is then covered with a thick varnish of caoutchouc, or with gutta percha, and submitted to the action of fire, in a muffle, when the organic matters are consumed and the metal left. 10. Lastly, the image, thus freed from the collodion and other organic matters, is covered with a silicic or boracic glaze, and submitted to an orange-red heat, which vitrefies it. This method is calculated to effect the perfect preservation of photographic images.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, May 2.

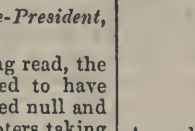
Professor W. A. Miller, *M.D., Tres.R.S., Vice-President, in the Chair.*

On the minutes of the previous meeting being read, the Chairman stated that the election announced to have taken place on the last occasion must be declared null and void, by reason of an insufficient number of voters taking part in the ballot. The name of another candidate who was then returned non-elected would also be again suspended, since the ballot in both instances was informal. The minutes were then confirmed. The following gentlemen then signed the statute book, and were admitted Fellows of the Society, viz., Messrs. Henry Weston Eve, C. R. A. Wright, William K. Waite, and J. W. Hudson, LL.D.

The candidates now proposed for election were Augustus Alfred Wood, 74, Cheapside; William Phipson Beale, barrister-at-law, Stone Buildings; and Alfred Coleman, Plough Court, Lombard Street. For the second time were read the names of Robert R. Tatlock, Millhouse, Kyles of Bute, and Walter William Fiddes, gas engineer, Sothernhaye, Clifton. For the third time were read the names of John Cargill Brough, 4, Norman Terrace, Stockwell; F. W. Peterson, of her Majesty's Mint, Calcutta, 51, Myddelton Square, London; and three other candidates. Before proceeding to the ballot, the Chairman said that the measure which had been under the consideration of the Council, and which was intended to raise the standard of qualification required for a member's admission into the Society, was not to be construed as being retrospective in its operation, and it would be manifestly inconvenient if the regulations were made more stringent in the case of the candidates proposed for election on this occasion. Upon the ballot being opened, the Fellows to the unusually large number of thirty-two recorded their votes, and the balls in certain instances had to be very carefully counted. The result was the return of Mr. Brough and Mr. Peterson as Fellows of the Society, but the other three candidates were declared non-elected.

The Chairman referred to the circumstance of so many of the leading members being in attendance at the Paris Exhibition and elsewhere, and said that a difficulty had been encountered in the attempt to provide formal matter in the shape of papers to be read; he would, therefore, invite communications from any Fellow or visitor in the room, who chanced to have any subject of interest in a sufficiently forward state to bring before the notice of the meeting.

Dr. Odling claimed the indulgence of the meeting in regard to the remarks he was about to offer, with a view of starting a subject for discussion. In the first place, he would mention, for the information of the manufacturing chemists, that the French had apparently succeeded in working out a great commercial problem with respect to the recovery of sulphur from the waste residues of the alkali manufacture. Great blocks of sulphur were shown in the Paris Exhibition which were said to have been prepared from this source, and it was proposed to employ it in making gunpowder and other sulphur products. So far as the speaker was aware, no published statement of the *modus operandi* had appeared, but it was generally believed that manganese in some form, and possibly the refuse of the chlorine retorts, was made available.* In the event of these anticipations being realised, there were vast accumulations of waste material in the north of England which could thus be economised. Turning to another topic of more abstract scientific interest, Dr. Odling observed that he found a difficulty in recognising the law of combination by saturation capacities, in what had been termed the "atomicity" of nitrogen. For instance, this element was found at one time entering into combination with *three* atoms of hydrogen, and thereby forming ammonia, whilst at other times, as in sal ammoniac, the nitrogen was united with *five* associated atoms. The constitution of these bodies might be thus represented:



According to this view, nitrogen had always five bonds, two of which, in the first example, controlled one another's activity, and all five were brought into play and united either with hydrogen or chlorine in the ammonia salt. In the union of chlorine and nitrogen, there must be an abstraction of heat, since the decomposition of the chloride of nitrogen was attended with the disengagement of a considerable amount of heat, yet, if chlorine be passed into ammonia, there was still a development of heat, and, nevertheless, the chlorine, we are told, leaves the hydrogen in order that it may unite with nitrogen, an element for which it has a very slight affinity. It might then, from this reaction, be doubted whether nitrogen was really pentatomic. Again, sodium exposed to air produces Na_2O, and this dissolved in water (with disengagement of heat) produced a hydrate, from which the water could not again be driven off by heat. But inasmuch as sodium gives out more heat than hydrogen by its union with oxygen, the conversion of the molecule of sodic oxide into hydrate would produce exactly as much cold as the conversion of the molecule of water into hydrate would produce heat. Thallium differed from sodium in these respects, and its hydrate lost water by the action of heat. These facts prove that sodium exerts upon the hydrogen an action which thallium does not. Other illustrations were quoted: thus in the slacking of lime there was great heat evolved, whereas the contrary result might have been expected, since there was, so to speak, "an unburning of the calcium." In the instances of barium and magnesium there seemed also something requiring explanation. The speaker concluded by offering an apology for having brought forward these considerations in an incomplete form, but he trusted that the attendant circumstances would justify his having taken such a step.

Professor Williamson remarked that chemists were very much in the habit of losing sight of one most important fact—viz., the changes of properties which elements undergo in combination. When they found that one element had got certain combining forces, they were apt to suppose that it must retain them when partially saturated by some other element. Thus, admitting that in potassic hydrate an atom of oxygen was combined, on the one hand, with an atom of potassium, on the other with an atom of hydrogen, it was not correct to assume that the force which bound it to the hydrogen was the same as that which bound it to each of the two atoms of hydrogen in water. The atom of oxygen in potassic hydrate was altered by its combination with potassium in such a way that it combined more powerfully

* It has been suggested that the sulphur may possibly have been extracted by the method of M. Emile Kopp described last year in the *Moniteur Scientifique*—Ed. *C. N.*

with hydrogen than in water. So also in sal ammoniac, an atom of nitrogen was united with five atoms, four of hydrogen and one of chlorine. By uniting with hydrogen it had become more basylous, and could hold chlorine more firmly than it could do when united only with chlorine. Professor Williamson added a few remarks on the subject of the word "atomicity." He was of opinion that all we know on the subject was represented by the word equivalence, and he recommended the retention of the word equivalence. "Atomicity" was used by some persons to denote an immutable equivalence, and in such sense was untrue and mischievous.

The Chairman entertained an objection to the use of the word "atomicity," since it implied a theory, whilst the term "equivalence" was merely a statement of the facts.

Dr. Thudichum said that in taking note of the fact that three successive speakers had expressed their dissatisfaction with the term "atomicity," he begged to state that he had never used it, but had from the beginning of his teaching described the property of atoms which it was intended thereby to signalise as "dynamicity." He recognised a priority of publication of the conception of the necessity for this change on the part of M. Würtz,† although this chemist had not made the change nor abandoned the questionable word. No one who valued logic could use expressions which signified the "indivisibleness of the indivisible," or the "undividedness of the undivided," with the effect of thereby defining anything; but the expression would appear still more illogical when it was considered that it was used to define a power the very essence of which, as it appeared from one point of view, was divisibility. Indeed, the expression "tomicity," if properly understood to refer to the power, and not to the matter or body of the atom, would be correct for a far greater number of cases than the same word with the privative "a" prefixed could ever reach. Those who had hitherto been most active in developing the theory of "atomicity" had implied that it was a power possessed by the atom absolutely, and that in cases where apparently only a portion of the maximum power which an atom could exercise was employed, the rest of its power was free, and open to engage itself. Late developments of science had, however, made it very doubtful whether this was a correct appreciation of the facts observed, and whether the changes in the amount of power exhibited by atoms were not actual changes of the amount of power possessed by them in concrete cases. Indeed, if he had rightly understood some theoretical considerations of Kolbe and of Würtz, these chemists seemed to admit that what they called "atomicity" was a changeable power of atoms, and that was the conclusion towards which his own studies and reflections had been driving him (Dr. Thudichum) for some time. The positive part of his opinion would appear from a few definitions which he begged leave to lay before the meeting. The idea of atom included, of course, that of element, in the chemical sense; and most chemists defined atom as the smallest quantity of an element that could exist in any chemical compound. All atoms manifested various qualities of power, and of some qualities of power many atoms manifested varying quantities. The first obvious power of atoms was that of polarity, the differentiation of which, in two opposite qualities (conveniently termed positive and negative, or + and −), explained the formation of the elementary molecule, or molecule consisting of two atoms homogeneous in every respect except that of polarity. Atoms further manifested chemism, or power to effect interchange of place, or substitution, or combination with heterogeneous atoms, polarity determining the place which each atom should take with reference to any other. Chemism is a stronger power than mere polarity; it separates the homogeneous molecule; but, in forming a new and heterogeneous molecule, it adds the entire amount of the polarity of the atoms employed to its own effective power. Thus, out of the combination of a molecule of hydrogen $\overset{+-}{(HH)}$ and a molecule of chlorine $\overset{+-}{(ClCl)}$, there result by the action of chemism two molecules of hydrochloric acid, equal in all respects except the polarity of their constituent atoms. The next quality which atoms manifested was dynamicity, which might be defined as the faculty to vary—that is, to decrease and increase—the amount of power of combination with other atoms. This power might be exercisable in multiple directions at the same time, but was not separable as to seat. For the intensity with which an atom was held, or exercised itself, in combination, dynamicity afforded as yet no measure. That intensity was no doubt the result of polarity, chemism, and dynamicity, and probably other influences, combined. But for the numeral quantity of power or the number of units of power of combination as measured by certain assumed standards, dynamicity afforded a correct expression. The unit or minimum of dynamis manifested by an atom, he termed monad; the greatest number of units constituted its monado-atomic equivalent, or full dynamis. The assumed standard of unit of dynamis hitherto accepted had been hydrogen, and the maximum number of units of power, or monads, hitherto attributed to any atom had been six, or once, in the case of iodine, seven. Now, the great error of the atomicity doctrine, most useful as it had been in evolving new facts and ideas, was this, that it assumed the number of monads of the atoms of each element to be invariable. The application of the doctrine of dynamicity to a broad field of chemical facts would, however, soon show that the dynamicity of atoms was variable, called forth or imparted by influences external to the atom, and similarly withdrawn. Heat, light, electricity, vital power, and pathogenetic power were such influences, governing not only the polarity and chemism, but also the dynamicity of atoms. Hydrogen manifested itself most commonly as monodynamic; it could be substituted by iodine and nitrogen. Now, iodine might be tridynamic, as in ICl_3; nitrogen might be tridynamic, as in ammonia. In the latter case the defenders of the invariable pentadynamicity of nitrogen would say that it was only active with three monads, and that two were free. In the case of iodine, however, when it substitutes hydrogen, the assumption that it only functioned with one monad out of its three was inconvenient, as it opened the door to the admission of the same variability on the part of hydrogen, and therefore iodine was here commonly admitted to be monodynamic. When nitrogen was made to substitute hydrogen, it lost apparently all dynamicity, though exercising only one, according to the assumption of the invariable monodynamic character of hydrogen. Out of such difficulties there were, no doubt, ingenious modes of extrication, such as the assumption of molecular powers on the part of combined groups of atoms not having the character of radicals. But the simplest cases were most simply explained by the hypothesis that the dynamicity of an atom was variable and dependent upon external influences calling forth its manifestation. Iodine had already been shown to be monodynamic and tridynamic; in imide, nitrogen was as monodynamic as when it substituted hydrogen in azobenzoic acid; in amide, nitrogen was didynamic; in ammonia the atom of nitrogen exhibited tridynamic combining powers; in some of the compounds lately discovered by Griess it showed tridynamic substitution power, replacing three atoms of hydrogen. The generalisation of this conception would no doubt destroy the simplicity of the present doctrines, but lead to a better appreciation of all the powers and influences determining combination or separation. In conclusion, the speaker apologised to the Society for the imperfection

† The reader is referred to the footnotes, p. 184 of Würtz's "Philos. Chimique." Paris. 1864.

of his remarks. They had been quite *impromptu*, and dealt with a great and difficult subject, which in many respects required consequential development. But he recommended his terminology‡ to the attention of the members, feeling sure that a slight familiarity with it would prove its great convenience.

Professor Foster agreed with Dr. Odling that, when the two molecules Na_2O and H_2O were converted into $_2NaHO$, the change undergone by one molecule was the converse of that undergone by the other, and, therefore, that it was difficult to understand that the quantity of heat developed in the one case should differ from that absorbed in the other; but he observed that there was no direct proof that the reaction in question was attended with any evolution of heat: when water acted on oxide of sodium, a great part of the observed evolution of heat was certainly due to the combination of NaHO with excess of water, and it remained to be proved that this action was not the source of the whole. The conversion of BaO and H_2O into BaH_2O_2 he regarded as a reaction not perfectly comparable with the above, since, in this case, the two molecules BaO and H_2O coalesced into the single molecule BaH_2O_2. With regard to the different behaviour of what appeared to be similarly constituted molecules when subjected to the same treatment, as, for example, that of sodic and thallic hydrates at high temperatures—an instance to which Dr. Odling had referred—he considered that the explanation of them was to be sought in the influence exerted by each atom in a complex molecule upon the properties of all the rest. To help in forming a definite conception of the way in which such an influence might be exerted, he suggested that a diatomic atom (such as O) might be compared with a magnet with its two poles, while monatomic atoms (such as Na and H) might be compared with a single isolated magnetic pole, if such a thing were capable of existing. Then, just as the south pole of a magnet would be strengthened by induction on bringing another south pole into contact with its north pole, so, by bringing an atom of sodium into contact with one pole of an atom of oxygen, the attraction of the other pole for atoms of a certain kind might be increased, although its attraction for sodium might be lessened. If this comparison of a diatomic atom with a magnet was admitted, he pointed out that, in all cases, if an atom of a given kind applied to one pole of a diatomic atom tended to strengthen the polarity of the latter, an atom of the same kind applied to the other pole would tend to weaken it in an equal degree; and hence that, as a general rule, if two symmetrical molecules, such as NaONa and HOH, came together, the forces with which the atoms were held together would be, on the whole, increased by an interchange of atoms such as would convert the above molecules into NaOH and NaOH. Professor Foster added that he did not offer these remarks as affording a solution of the difficulties pointed out by Dr. Odling, but simply as indicating a direction in which he thought such a solution might reasonably be sought for.

Mr. Chapman, in allusion to an illustration made use of by the last speaker, said that if two bar magnets were placed end to end, the north pole of one being adjacent to the south pole of the other, the sustaining power of the free end of the lower magnet was *not* augmented; but that if they were laid parallel and alongside, with similar poles adjacent, the magnetic energy of each magnet would be greatly increased. (This statement was received with manifest indications of dissent.)

Professor Wanklyn had likewise a great objection to the continued use of the word "atomicity." Ammonia and sal-ammoniac presented differences in constitution which were not easily explained, but it might happen that the *hydrogen* in these compounds had different values.

The meeting was then adjourned until Thursday, the 16th instant.

‡ In Dr. Thudichum's Tables of New Atomic Weights, Molecular Weights, and Functional Types for the Lecture-room and the Study, published by Hardwicke, Piccadilly, this terminology is adopted, and the theory of the variable dynamicity of atoms indicated on the basis of some of the best-established facts.

ACADEMY OF SCIENCES.

May 7, 1867.

(From our own Correspondent.)

M. Bertrand read a very favourable report on the memoir of M. A. Cornu, entitled, "*Théorie Nouvelle de la Réfraction Crystalline de Fresnel.*" The principal conclusions of the report were, that the luminous vibrations were normal to the plane of polarisation, as Fresnel and Cauchy announced a long time ago, though the direct proofs hitherto proposed are open to discussion.

M. Charles Robin resumed the result of his researches on the origin, development, and completion of the dorsal cord, called the cord of Owen.

The Academy proceeded to the election of a Correspondent for the Geometrical Section in place of M. Rieman. The choice almost unanimously fell upon M. Plucker, of Bonn, the well-known Professor. He received the Copley Medal of the Royal Society for 1866, and many honours which we cannot now enumerate.

M. Salmon, of Dublin, author of "Lessons in High Algebra," &c., obtained the vote left by M. Plucker.

The Academy then proceeded to the election of an Anatomical and Zoological Correspondent. M. Siebold, brother of the Japanese traveller, was elected by a large majority.

M. Balard presented an ice-making machine, made by M. E. Carré, brother of the well-known inventor of the ammonia one. Its action depends on the absorption of vapour of water by sulphuric acid, and the congelation is most rapid, as soon as the vacuum is produced.

M. Regnault, in the name of M. Soret, of Geneva, communicated a new note on the determination of the density of ozone. Experiments of absorption lead to the conclusion that the density of ozone is one and a half times that of oxygen. He applied Graham's law of diffusion—viz., that the diffusion takes place in the inverse proportion of the square of the density. He then diffused two mixtures—one of oxygen and chlorine; the other of oxygen and ozone. Thus compared, the density of ozone to that of chlorine or oxygen was found to be 1 : 5.

NOTICES OF BOOKS.

Discorso di Apertura del secondo anno della Facoltà di Chimica. Letto dal Fondatore, Prof. Carlo Cassola. Napoli. 1867.

The address of the President at the opening of the second year of a chemical college could hardly, our readers might say, contain much novelty, or any details which they could not note down beforehand. Of course he would give a general glance at the position of chemistry, the progress of discovery, and the prospects of the institution where the science was cultivated and taught. The above address does nothing of the kind. Italy has been too long under despotic rule to have retained her old courage for scientific inquiry, and now that she has happily reconquered liberty, she is only beginning to see the necessity of cultivating science as one of the most urgent means of cultivating the sources of national wealth. Hence this address is most curious and suggestive; its elementary character, its all but juvenile pretensions, have something of hope and encouragement in them; so that in laying the substance of this discourse before our readers we are sure they will join us in an expression of sympathy for young Italy, and in the hope that her intelligent sons may see the importance of the new institution and encou-

rage it in the only way that can lead to durable success—namely, by earnest study and hard laboratory practice.

The address begins by referring to the backward condition of Italy consequent on political misrule, and the paramount duty of every Italian to acquire political independence for his country. That desirable event having been accomplished, the next struggle was the endeavour to bring up their country to the level of more civilised nations. How was this to be done? Not by relying on the Government, but by their own exertions, in constructing railroads and other means of communication, developing the riches of the soil, encouraging industry; taking, in short, as their model, the Anglo-Saxon race—America and England.

The President goes on to show how false is the system of national prosperity that produces little and consumes much, exports nothing, imports everything; that produces few or no results of public education, while the population is uneasy and miserable. Trade and commerce are depressed, and those who should foster them are discouraged, because the system pursued is a false one. What is wanted for Italy is the development of her internal riches, and the knowledge how to apply science to her everyday wants.

"Banished from my native country by the political events of 1848-9, I have laboured and studied in different parts of Europe, in Asia, and the two Americas, to understand the secret of national prosperity. I returned to Italy, and excited my countrymen to follow the example of the stranger. I was laughed at! By good fortune I have had the privilege of founding this centre of instruction and research, although opposed by the Government and the municipality. The chief object of this Faculty of Chemistry is to instruct Italians in analytical chemistry and its application to industry, and then to distribute the men so educated over the country. Another object is to bring the scientific Italian out of his retirement and make his pulse beat in unison with that of his fellow-citizens—to win him, in fact, to the side of national industry and make him more esteemed in his native land."

Italy is beginning to feel the importance of the call. Various municipal and other bodies have sent minerals to be examined, and the Faculty is already in a condition to declare that Italy has undeveloped wealth in every kind of industry. Search has been made for coal, that great motive force, and in spite of the opposition of Government and of the municipality of Naples (expressions that occur more than once, and which we confess we do not understand) the province of Naples can supply that great need.

He then goes on to show how to make the exports and imports more nearly balance each other. The imports in Naples and the surrounding districts amounted to 200,000,000 lire per annum,* and the exports to only 36,000,000. He proposes to work the metallic ores of the country by means of companies, to extend railroads, &c.

The School of Chemistry, the only one in Italy (!), was founded in 1866, and has already acquired much precise knowledge as to the natural wealth of the country. It is strongly recommended that the youth of Italy be educated in the theory and practice of the sciences, in facts and observations, and not in dry themes. The Faculty has already supplied two Lyceums with the chemical apparatus required for instruction, and the University has also sought its aid. It has sent several chemists to different parts of Italy, and it carries on a wide correspondence with persons who require information on scientific subjects.

The analyses performed by the Faculty had been liberally paid for with one exception, and that was on the part of the Government. One of the departments sent a liquid to the Faculty to know if it were adulterated, and on returning the analysis the fee demanded was refused, on the ground that the Faculty was a public department, although all its documents bear the words "*iniziativa privata.*" It is stated as one of the worst features of modern Italy that it grudges the scientific man his fee, while the number of useless officials that devour the public wealth is legion.

An exhibition of national products would be useless until there is a larger number of producers. It is to be deplored that many Italians are gratified with an honourable mention and a poor medal, while the maccaronis, once especially a native product, are now made of Russian flour, and are eaten with a French fork off an English plate.

It appears that the King had offered the President a house and 400 lire per annum if he would establish the Faculty at Turin, while both house and endowment were refused in Naples. "Such," he says, "is the Government patronage of science in Italy, at a time when the Prussian Government was expending 500,000 lire on the building alone of a laboratory of instruction in Berlin." He calls upon the people to get out of the leading strings of the Government, and to think and act for themselves, although, somewhat contradictory to this advice, he suggests that a law be passed requiring every commune to set aside an annual sum for the purposes of scientific inquiry.

There are other suggestions, sensible enough in their way, but remarkable to us only for being so obvious. On the whole, we are gratified with the manly spirit of the address, in spite of a little too much self-assertion and recrimination, and think it creditable to the Government that young Italy can enjoy such freedom of speech. The very elementary nature of the address, and of the proposed remedies, show how degraded poor Italy had become under long years of political misrule. That there should be only one establishment in Italy capable of conducting a chemical analysis, and that establishment a private one, from which a University is taking lessons, is indeed a commentary on the oft-repeated proposition that when a nation loses its political freedom it must part also, sooner or later, with its science, its literature, and its art. It cannot become enslaved in body without being also enslaved in mind.

* The lira is worth 9¾d.

Chemical Notes for the Lecture Room. By Dr. Wood, F.C.S. London: W. and H. Warr and Co., Featherstone Buildings, Holborn. 1867.

For the matriculation examination of the University of London, an examination that has acquired of late years very considerable importance, a knowledge of chemistry is insisted upon quite as fully as a similar knowledge of any other branch of education. If a candidate be rejected for not gaining the minimum number of marks in any one subject, he has to pass in all the others again at a future examination. Last year 641 candidates presented themselves, and of these 334 were rejected; in 1865, 397 out of 616. An ignorance of chemistry is a very fertile cause of these rejections, and candidates generally complain of this subject as being one of "the stiffest." Very few fail, it seems, in mechanical philosophy. This is accounted for by the existence of a book, recognised as being the one necessary to work up thoroughly, and almost universally employed in the latter subject; while in chemistry the beginner, in an absolute sense, confuses himself by a mass of details, without the corresponding impression from seeing lecture experiments. Dr. Wood has endeavoured to prepare a short text-book on the subjects required, to answer the same purpose that Newth's "Mechanical Philosophy" now serves in another subject. We think that he has succeeded in a difficult task, but those who read the book will require to know it well. We need not talk of Dr. Wood's knowledge as a chemist, but we may mention that as a teacher he is widely known, and few chemists have more knowledge of what is required by candidates for the before-mentioned examination, and for whom the book is almost specially framed.

It is a capital guide book for lecture experiments, although, as the author remarks, it is in nowise intended "to supersede the excellent works of Miller, Roscoe, and others"—we presume that he means for this particular examination. It will form, as he remarks, a book of easy reference. As an additional recommendation, the wording of expressions and symbols are "the very latest out."

Guide to Croft Spa. Third Edition. Darlington: J. and J. Burney, *Telegraph* Office, High Row. 1866.

In the Chemical News, September 14, 1861, a detailed account was given of the chemical properties of the waters of this spa. It will be seen from that notice that three of the springs there contain more sulphuretted hydrogen than any other mineral springs in England. We are glad that the prosperity of Croft Village has called for a third edition of this very complete guide to its spa.

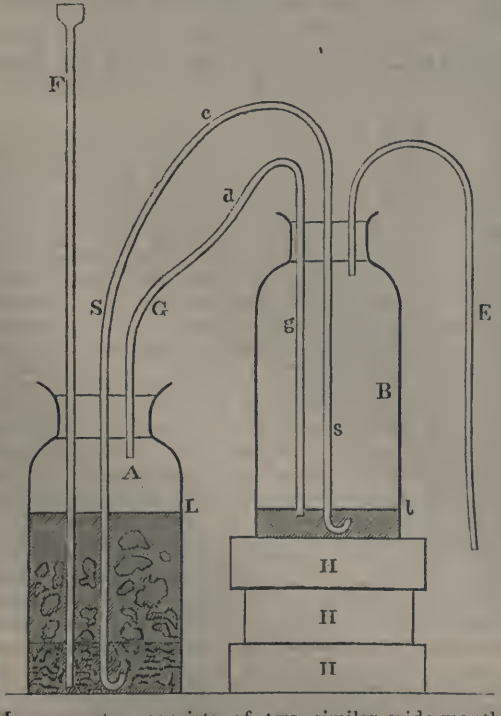
CORRESPONDENCE.

Improved Sulphuretted Hydrogen Apparatus.

To the Editor of the Chemical News.

Sir,—I venture to describe a modification of apparatus for generating sulphuretted hydrogen, which will, I trust, recommend itself to the laboratory on the grounds of compactness and cheapness, combined with effectiveness.

It consists essentially of a generator and a wash-bottle united (in addition to the ordinary connexion) by a siphon, whose legs dip to the bottom of each vessel; it occupies, therefore, the same space as the simplest arrangement, while the production of gas may be rapidly arrested or controlled at pleasure without the escape of noxious effluvia. Its cost of construction need not exceed one shilling, while it affords even greater conveniences than the more costly adaptation described at p. 152 of the *Journal of the Chemical Society*, 1864.



My apparatus consists of two similar wide-mouthed bottles, A and B, whose bungs (or, preferably, whose caoutchouc capsules) are pierced each by three holes. A is the generator, supposed in action; B is the wash-bottle, which serves also, during inaction, as a reservoir for the exciting acid; F, a tall thistle-headed funnel passing to the bottom of A, by which it is charged, and which serves also as a safety-vent; S, *s*, the siphon limbs, which dip to the bottom of each vessel, and are slightly recurved at the orifices; *c*, *d*, caoutchouc connectors; G, *g*, the transit pipes for the gas as generated, the former terminating at the top, the latter at the bottom, of their respective vessels; E, the eduction pipe; H, blocks used to relatively raise or depress each bottle as occasion requires.

Previous to operation, A is filled a quarter full of broken glass; on this are laid lumps of ferric sulphide, which are thus prevented from choking the ends of F and S; acid is poured in through F till A is three-quarters full; the siphon is then charged by nipping the other bend *d*, when the pressure of gas formed in A should be suffered to force the contained liquid over the bend *c* into B, till the mouths of *g* and *s* are covered, and the acid stands at the same level in both bottles, as in the figure L, *l*. B is then raised on the blocks H, and *d* is unnipped, when the gas will commence flowing in its normal direction through G *d g*, and, bubbling through the wash-bottle B, will pass out at the eduction tube E. When it is desired to stop the action, A is raised on the blocks, and B depressed; the former will then be emptied by the siphon into the latter; the reverse will take place, if, with a view of re-exciting the sulphide, the levels be again interchanged.

Your readers' ingenuity will suggest how, by varying the elevations, the flow of gas may be regulated to a nicety, or the charge of acid renewed without opening the bottles or emitting any smell. The eduction tube should, after traversing the solution to be impregnated with H_2S, always finally dip into a bottle of strong liquor ammoniæ, which will absorb any excess of unused gas, thus furnishing a useful laboratory reagent as a by-product.

Should the siphon become inoperative from gas collecting in its bend, which may occur through inadvertently over-emptying either bottle, or from effervescence passing up its limb S, it may be readily recharged as at starting.

Such an arrangement is of course equally applicable to other gases of daily use in the laboratory, for each of which such an inexpensive apparatus might be reserved.

I am, &c. B. W. Gibsone, M.A., B.Sc.

Eaton Square, S.W., April 8.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Periodic Acid, its Basicity.—C. G. Lautsch has examined a number of periodates without being able to give decisive evidence on this point. He is inclined to the opinion that this acid is pentatomic and tribasic, notwithstanding that a difference between atomicity and basicity has not yet been established in the case of any mineral acid. The question might be conclusively answered if it were possible to introduce into the molecule of the acid alcohol and organic acid radicals, but the oxidising power of the acid is so great that it is doubtful whether it is possible to effect this replacement.—(*Journ. prakt. Chem.* c. 65.)

Cobalt and Nickel, Equivalents of.—Dr. E. v. Sommaruga. The determination of the equivalent of cobalt was performed on Gibb's and Genth's purpureo-cobaltic chloride; this salt was dried perfectly by many hours' heating at 110°, weighed, heated till the ammonia, ammonic chloride, and water were wholly expelled. The resulting very hygroscopic cobaltic chloride was then reduced by hydrogen; the metallic cobalt was weighed, and gave a mean of seven determinations 29·965, maximum 30·009, minimum 29·916.

The nickelo-potassic sulphate was used for the deter-

mination of the equivalent of nickel. To prepare this salt, commercial nickel was dissolved in dilute sulphuric acid, to which nitric acid was occasionally added; a quantity of potassic sulphate, insufficient to combine with all the nickelic sulphate, was added to the filtered solution; the solution was evaporated to crystallisation, and the crystals, after washing out the nickelic sulphate, were recrystallised several times. The final product worked on still retained traces of cobalt, but no other impurity. The crystals were dried at 100° and weighed; the sulphuric acid was determined as usual, and the equivalent of nickel calculated from the weight of baric sulphate. The mean of six experiments was 29·013; maximum, 29·079; minimum, 28·911. The proximity of these numbers to those obtained by R. Schneider from different experimental bases supports the author in assigning to cobalt the equivalent 30, to nickel 29.—(*Sitzungsber. Akad. Wien*, June, 1866.)

Vapour Density, Determination of.—R. Bunsen. As the omission of one minute detail would, in performing determinations by this method, render the result worthless, an abstract of this wonderful paper would be of little value, and no abstract could give an idea of the astonishing delicacy of the operations described; we therefore refer readers to the original, remarking that with carbonic dioxide, six experiments, in each of which less than ·35 gramme was employed, a mean 1·527, maximum 1·529, minimum 1·525, were found. Regnault, working on 19 grammes, found 1·529.—(*Ann. Chem. Pharm.* cxli. 273.)

Fatty Acids, Chloro-derivatives of (C=12).—Dr. W. Schlebusch. Hypochlorous acid does not unite with fatty acids, but introduces chlorine into their molecule; the acetic acid chloro-derivative is difficult to obtain; valeric acid gives chlorvaleric acid, described by Clark and Fittig. Valerolactic acid and its baric, cupric, and argentic salts are described. Butalanine $C_5H_{11}O_2N$ was obtained by heating the crude chlorvaleric acid with absolute alcohol saturated with ammonia. After a few hours' exposure in sealed tubes to 120°, the solution was evaporated to expel ammonia and alcohol, heated with baric hydrated oxide to decompose ammonic chloride, freed from baric salts by sulphuric acid, and evaporated to crystallisation. Butalanine combines with acids. With chlorhydric acid transparent plates are formed.—(*Ann. Chem. Pharm.* cxli. 322.)

Carminic Acid (C=12).—H. Hlasiwetz and A. Grabowski. Carminic acid, when boiled with dilute sulphuric acid, splits into carmine red and sugar; the latter reduces Trommer's solution, and gives Pettenkofer's reaction, but neither ferments nor acts on polarised light; traces of it are dissolved by alcohol. Dried at 50°, its formula was $C_6H_{10}O_5$; at 100°, $C_6H_8O_4$.

Carmine red, $C_{11}H_{12}O_7$, is a dark purple amorphous substance, reflecting green light, soluble in water and alcohol, with a fine red colour; insoluble in ether. Like carminic acid, it pertinaciously retains traces of phosphates; its alcoholic solution, when treated with alcoholic potash solution, deposits the whole of the carmine red as $C_{11}H_{10}K_2O_7$, from which the corresponding baric and calcic compounds were obtained. Powerful reducing agents perfectly decolorise the solution of carmine red, but the resulting body could not be separated in a pure state. Fused with potash solution of appropriate strength, carmine red gives oxalic and succinic acids, and coccinin—probably $C_{14}H_{12}O_5$—a body resembling chinon. Its crystals polarise light, are insoluble in water, easily soluble in alcohol, difficultly so in ether. Coccinin dissolves very easily in dilute alkaline solutions, and in such solution is one of the most sensitive bodies to the action of oxygen. The solution is at first yellow, then violet, finally a magnificent purple red. Few bodies give rise to so many phenomena of colour as coccinin.

From the splitting of carminic acid into carmine red and sugar, perhaps Schützenberger's is the nearest to the real formula—probably $C_{17}H_{18}O_{10}$—of that much-investigated body.—(*Ann. Chem. Pharm.* cxli. 329.)

Rufigallic Acid, a Derivative of (C=12).—G. Malin. Rufigallic acid was fused with potash, and gave among other things a straw-coloured body crystallising in very slender needles soluble in boiling water, in alcohol, and in ether, sparingly soluble in cold water, reacting acid, decomposed by heat; its aqueous solution reduced argentic and alkaline cupric solutions; it did not appear to combine very definitely with anything. Its formula is $C_6H_4O_3$, and its name oxychinone.—(*Ann. Chem. Pharm.* cxli. 345.)

Resins rendered Soluble.—H. Violette. Copal and other refractory resins are soluble in oil of turpentine, &c., if they have been heated for 15—20 minutes to 350—400°, of course in closed vessels. The best way of operating is to heat the resin for a few minutes in an open vessel; 5 or 6 per cent. of water are by this means expelled. The vessel is then closed, and the heating continued. The product gives very excellent varnishes. To avoid the necessity of heating the varnishes made as described, in order to brighten them, the oil, &c., which it is intended should be used, may be heated together with the resin. The product then simply needs dilution.—(*Ann. Chim. Phys.* [4]. x. 310.)

Phosphorous Acid (O=16).—Rammelsberg. The examination of compounds of phosphorous acid with dyadic metals leads to the conclusion that this acid exists in three states, corresponding to the ortho-, pyro-, and meta-phosphoric acids. Thus the (K′, Na′, Am′), together with the (Pb″, Cu″, Cd″, Mn″, Co″, Ni″?) salts, which may respectively be typified by HR'_2PO_3 and $HR''PO_3$, point to $\left.\begin{matrix}H_2\\H(PO)''\end{matrix}\right\}O_2$, corresponding to metaphosphoric acid, The (Ba″, Sr″, Ca″, Ni″?, Zn″?) salts give $H_8P_2O_7$, otherwise $\left.\begin{matrix}H_6\\2H(PO)''\end{matrix}\right\}O_5$, corresponding to pyrophosphoric acid, and the magnesic salt, though less decisively, indicates $\left.\begin{matrix}H_4\\H(PO)''\end{matrix}\right\}O_3$, corresponding to orthophosphoric acid. An ethylic salt, in which the hydrogen is wholly replaced by ethyl, is represented by $\left.\begin{matrix}2(C_2H_5)\\C_2H_5(PO)''\end{matrix}\right\}O_2$. It is to be observed that whilst the acid radical in phosphoric acid is triadic, that in phosphorous acid, having one bond saturated by H, is only dyadic H(PO)″; similarly the acid radical of hypophosphorous acid is only monadic $H_2(PO)'$. —(*Monatsber. Berl. Akad.* Aug. 1866.)

Ethylic Chloracetate, Action of Ammonic Carbonate on.—W. Heintz. The acids of the lactic series possess at once the functions of acids and alcohols, their basicity remaining unaltered by the replacement of hydrogen by acid radicals; and as under the influence of dyadic metals two molecules of acid will unite in order to furnish two replaceable atoms of H basylous, so under the influence of acid radicals should two molecules unite to furnish H_2 chlorous. The preparation of ethylic succinyl-lactate proves the correctness of this view. Dyadic carbonyl not having been used in a similar reaction, an attempt was made to effect this molecular combination by means of sodic carbonate, but the product was too small to be useful. Ammonic carbonate was therefore employed, it seeming likely that its volatility would assist the reaction, but an examination of the products obtained showed that carbonic acid did not intervene in the reaction which really did occur, the result of the experiments being that ethylic tri-, and probably di-, glycol-amidate were produced.—(*Ann. Chem. Pharm.* cxli. 355.)

Cupric Persulphide (Cu=63·5, S=32).—A. Gescher. Bloxam's body $Cu_2(NH_4)_2S_7$ was prepared by making a solution of ammonic persulphide of such strength that a sample of it, mixed with an ammoniacal solution of cupric sulphate, deposited on standing red crystals quite free from black cupric sulphide. The right strength being

attained, the solutions were mixed in bulk. To the crystals so obtained the formula $2CuS_3 + (NH_4)_2S$ is attributed.—(*Ann. Chem. Pharm.* cxli. 350.)

MISCELLANEOUS.

Death of Walter Crum.—Many of our readers will hear with regret of the decease of Mr. Walter Crum, which took place on the 4th inst., at Thornliebank. Mr. Crum had been for more than twenty years a Fellow of the Royal Society. His papers, chiefly on subjects connected with calico-printing, were numerous, and bore the stamp of great talent and originality; we may especially mention his researches on Indigo, on the Acetates of Alumina, on Mordants in Dyeing, on Cotton-fibre, &c. By his death the Chemical Society loses one of its original Fellows and a respected Vice-President.

Analysis of Earth eaten in Borneo.—Some few years ago the manager of the Orange-Nassau colliery, near Zandjermasin, in the Island of Borneo, found that many of his workpeople (natives) consumed large quantities of a kind of clay; a sample of this material was forwarded to Batavia for analysis, and the following is the result in 100 parts:—

Pitcoal resin (organic matter volatile at red heat)				15·4
Pure carbon	,,	,,	,,	14·9
Silica	,,	,,	,,	38·3
Alumina	,,	,,	,,	27·7
Iron pyrites	,,	,,	,,	3·7
				100·0

We remind our readers that the eating of clay is a custom to which savages—or, at least, human beings of a very low degree of development—are freely given in various parts of the world. No other analyses of any of the substances used as such have been made, or at least, if made, they have not been published. The resident military medical officer at the above-named colliery is strongly inclined to consider it the duty of the manager to eradicate and discountenance this habit of the workmen, as it appears to injure their health.

Meetings for the Week.

Tuesday, May 14.

Royal Institution, 3 p.m. Professor Miller "*On Spectrum Analysis.*"

Royal Medical and Chirurgical Society, 8½ p.m.

Photographic Society, 8 p.m.

Wednesday, May 15.

Society of Arts, 8 p.m.

Pharmaceutical Society, 8 p.m. Anniversary.

Thursday, May 16.

Royal Institution, 3 p.m. Professor Huxley "*On Ethnology.*"

Royal Society, 8½ p.m.

Chemical Society, 8 p.m.

Friday, May 17.

Royal Institution, 8 p.m. Professor Odling "*On Absorption of Gases by Metals.*"

Saturday, May 18.

Royal Institution, 3 p.m. Professor Huxley "*On Ethnology.*"

NOTES AND QUERIES.

Colours from Caramel.—Sir,—Perhaps the following information may be of use to your correspondent:—The secret consists in using glucose and heating it with an alkali. For vinegar, carbonate of ammonia is required, as a fixed alkali produces turbidity. 120 lbs. of glucose require 6 lbs. of carbonate of ammonia and 6 lbs. of water. Heat together in a metal boiler till the glucose is of the desired colour, keeping the mixture well stirred. Then add 30 or 40 lbs. of warm water poured in a thin stream.—F. Thompson.

Glass Drilling.—A correspondent, D. F., informs us that the process for working glass with files, drills, or other tools of steel, moistened with dilute sulphuric acid, as given by Dr. Lunge in the last number of the Chemical News, was the subject of a patent taken out by Maudsley some years back.

Nitro-benzol.—Sir,—In reply to "Manufacturer," I beg to inform him that I have prepared nitro-benzol nearly colourless, and with a pure fragrant odour, by distilling it much below its boiling point in a current of steam. The first portions, which contain benzol, &c., are to be rejected.

Chinese Blue.—We have received several communications on this subject, in answer to a query in our last number. If "R. H. W., Manchester," will send an address, they shall be forwarded.

Light Coal Oil.—Sir,—Have any of your readers tried a plan of mixing the light oil obtained from coal tar with a solution of chloride of lime, and submitting the mixture to distillation? If so, what changes have been noticed, and what was the action on the sulphur compounds?—M.

Caramel Colours.—If "E. A., Glasgow," will send his address, we will forward several communications which have arrived on this subject.

Calico Printing.—Sir,—I have spent over three years in trying to improve various colours now in use by calico printers and dyers. I shall be glad if you could assist me in obtaining a little ready money for the following important discovery:—I can print on cotton goods a mordant that will produce a perfectly fast mauve, with, or at the same time as, garancine work, more fast and bright than any produced previously. I can dye all aniline colours faster and brighter than they have ever been done, and at a much less expense, on any kind of fabric. I can also produce the same shade of colour on mixed goods at one operation, and which is both cheap and simple. I will render every explanation necessary to any one applying through you or your valuable paper, and give any security and guarantee.—J. K. M.

ANSWERS TO CORRESPONDENTS.

*** All *Editorial Communications* are to be addressed to the Editor, and *Advertisements* and *Business Communications* to the Publisher, at the Office, 1, Wine Office Court, Fleet Street, London, E.C. *Private* letters for the Editor must be so marked.

*** In publishing letters from our Correspondents we do not thereby adopt the views of the writers. Our intention to give both sides of a question will frequently oblige us to publish opinions with which we do not agree.

Vol. XIV. of the Chemical News, containing a copious Index, is now ready, price 11s. 6d., by post, 11s. 6d., handsomely bound in cloth, gold-lettered. The cases for binding may be obtained at our Office, price 1s. 6d. Subscribers may have their copies bound for 2s. 6d. if sent to our Office, or, if accompanied by a cloth case, for 1s. Vols. I., II., and VII. are out of print. All the others are kept in stock. Vol. XV. commenced January 4, and will be complete in 26 numbers.

Owing to the length to which our report of the Chemical Society extends, we are compelled to omit articles by Dr. Muspratt, Dr. Maisch, and others, together with several reviews, reports, and letters.

W.—Crucible is derived from the Latin *crucio*, to torture or twist.

F.R.A.S.—The letter has been forwarded.

Townsend, Hook, and Co.—The address shall be sent. The author is preparing an article on the subject for these pages.

W. Beckett.—The syrup of orange and quinine appears likely to be of value in cases where orange wine and quinine would be injurious to the system.

Constant Reader and *Another Person.*—Sunlight shining on a fire will not put it out nor prevent combustion. The explanation of the popular opinion on this point is, that the light of the sun is so immeasurably superior to that of the fire, that the latter appears to lose its brilliancy when sunlight falls on it, and to an ordinary observer would seem dead.

T. S.—We should be pleased to receive the information in a form suitable for publication.

M. M. Soc.—The animal matter may be removed from the sections of bone by soaking them in caustic potash. The alkali must be well washed out before mounting the sections. Canada balsam is best for the latter purpose.

Books Received.—"The Calculus of Chemical Operations; being a Method for the Investigation, by means of Symbols, of the Laws of the Distribution of Weight in Chemical Change. Part I. On the Construction of Chemical Symbols." By Sir B. C. Brodie, Bart., F.R.S.—"Dr. Ure's Dictionary of Arts, Manufactures, and Mines." Edited by Robert Hunt. Vols. I., II., and III.—"A Dictionary of Science, Literature, and Art." By W. T. Brande and Rev. G. W. Cox. Vols. I., II., and III.

Communications have been received from Dr. Adriani; J. H. Swindells; A. Jaeger; T. Sherlock; J. Kenyon; R. Hulse; J. C. Bell, F.C.S.; G. Thompson; Lewis, Ash, and Co.; A Subscriber; A Constant Reader; James Browne and Son; E. Tate; Messrs. Huskisson and Son; P. Squire; Johnson and Sons; Another Person; Gaskell, Deacon, and Co.; Allhusen and Son; May and Baker; J. R. Haas and Co.; W. Beckett; Townsend, Hook, and Co.

ELECTION OF FELLOWS AT THE CHEMICAL SOCIETY.

It was suggested last week that it would probably be necessary to alter some of the By-laws regulating the admission of Fellows into the Chemical Society, and we stated that the problem to be solved was how to guard against the admission of unfit persons, and at the same time to prevent the ballot becoming an organ for the gratification of personal pique. On looking more carefully into the Charter and By-laws of the Chemical Society, it appears that there is to be found a very simple solution of the latter part of this problem. Attention being drawn to the subject, it has not failed to strike most persons as manifestly unjust that the decision on an important question, brought before a meeting of the members, should be determined according to the wishes of the minority; and it shows how harmoniously the Society and its officers have hitherto worked together that this hardship has never been felt before. On his admission, each Fellow received the regulations of the Society, together with sundry other formal documents; but we venture to say that not many looked at them a second time, and few will now be able to lay hands on a copy of the Charter and By-laws, to which we now propose to direct attention. When everything is going on smoothly, the laws and regulations of the Society are dormant.

It now appears that for many years the Society has been acting contrary to the Charter, in electing Fellows, honorary and foreign Members, and Associates, according to the existing By-laws.

By the third paragraph of the Charter of Incorporation, granted to the Society in 1848, it is declared—

"That at all General Meetings and meetings of the Council the majority present and having a right to vote thereat respectively shall decide upon the matters propounded at such meetings."

Again, the concluding paragraph of the Charter declares,

"That no resolution or by-law shall, on any account or pretence whatsoever be made by the said body politic and corporate in opposition to the general scope, true intent and meaning of this our Charter; and that if any such rule or by-law shall be made, the same shall be absolutely null and void to all intents, effects, constructions, and purposes whatsoever."

Now, it is very evident that the By-law, making the election of a candidate depend upon the votes of three-fourths of the Fellows present, is in direct contravention to the "true intent and meaning" of the first-quoted paragraph of the Charter; and therefore such By-law is, according to the terms of the second citation from the Charter, "absolutely null and void to all intents, effects, constructions, and purposes whatsoever."

But it may be argued that the third paragraph of the Charter refers only to anniversary meetings or extraordinary meetings of the Society. An attentive examination will, however, show that by the term "general" meeting is intended that which is now commonly called an "ordinary" meeting. The term "*ordinary* meeting" strictly means *regular* or *customary* meeting; a *general* meeting means one public or common to the whole of the Fellows. Custom has sanctioned the omission of the word "general" as qualifying the ordinary meetings, but it is still retained in By-law, which speaks of an *extra*-ordinary general meeting, which, logically and grammatically, can only mean a *general meeting* held *extra*, or in addition, to the *ordinary* bimonthly meetings.

The term "general meeting" occurs several times in the Charter, but nowhere do we find the terms "ordinary" and "anniversary" meetings. When, however, we refer to the regulations of other learned societies, no longer can there be any doubt as to the meaning of the term "general" meeting. In the Charter of the Royal Society no mention is made of meetings of the members, ordinary, extraordinary, or general. But in the Charter of the Zoological Society the term "general" meeting is used in a sense applicable only to ordinary meetings; and in the By-laws the monthly meetings of the Society are invariably spoken of as "general meetings," or "ordinary general meetings." In the Charters of the Linnæan and Geological Societies likewise the term "general meeting" is used to express the ordinary meetings of the members, and in the By-laws these are invariably termed "general" meetings; the 9th section of the rules of the latter Society, in fact, state that "the *general* meetings to be held by the Society shall be of three kinds:—1. *Annual*; 2. *Special*; 3. *Ordinary*." It cannot, therefore, be doubted that the term "general" meeting in the third paragraph of the Charter of the Chemical Society means the same as the term "ordinary" meeting does in the By-laws.

No one, we imagine, will dispute that the election of Fellows is a "matter propounded" at a meeting upon which the "majority present" are to decide. On the contrary, the question as to whether a candidate is to be admitted to the Fellowship of the Chemical Society is a very important matter propounded to those present who have a right to vote, and the question, above all others, which should be carried by a numerical majority.

In strict logical interpretation, therefore, those candidates who were blackballed at the recent meetings of the Society were excluded from the Fellowship in error. A numerical majority of voters were in favour of their admission, and at the present time the blackballees are as strictly entitled to the letters F.C.S. as are any of the blackballers.

We confess we see only one course to be pursued in respect to the By-laws which remit the decision on such important matters as the election or removal of Fellows to a small minority, in opposition to the wishes of the great bulk of those present. Strictly speaking, these restrictive By-laws never had any legal existence, and they should at once be replaced by others in conformity with the Charter.

One half of the problem now under discussion—that of preventing voting by ballot becoming an organ for the gratification of personal pique—has solved itself in a manner which leaves nothing to be desired. The first

part of the question—How to guard against the admission of unfit persons into the Society—is one in which Council and Fellows are free to act, for the Charter specially provides that they "may alter, vary, or revoke, and may make such new and other By-laws as they shall think most useful and expedient for the said body politic and corporate, so that the same be not repugnant to these presents." Thus the way is clear to a satisfactory settlement of the recent unwarrantable proceedings and the permanent prevention of their recurrence, and to the establishment of safeguards against the degradation of the Fellowship of the Chemical Society.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On the Direct Production of Stilbene from Bitter Almond Oil, by C. GREVILLE WILLIAMS, *F.R.S.**

STILBENE was obtained by Laurent by the distillation of hydride of sulpho-benzoyle, according to the equation—

$$\underbrace{8C_7H_6S}_{\text{Hydride of sulpho-benzoyle.}} = 2CS_2 + 3H_2S + 2\underbrace{C_{14}H_{12}}_{\text{Stilbene.}} + \underbrace{C_{26}H_{18}S}_{\text{Thionessal.}}$$

The simplicity of the relation between hydride of benzoyl and stilbene made me conceive that the latter might be produced directly from the former; thus—

$$2C_7H_6O + 4Na = C_{14}H_{12} + 2Na_2O.$$

Experience has completely confirmed this supposition. The reaction, however, as might be expected, does not take place without the formation of other products. In fact, the amount of stilbene produced is so small, and the difficulties in the way of the separation of the substances produced are so considerable, that I should have delayed publishing my results in their present state had I not seen that Claus† is working in a somewhat similar direction. However, as he employs sodium amalgam and an etherial solution of hydride of benzoyl, instead of hydrocarbons, he obtains bodies containing oxygen. One of the substances produced in the manner indicated is the salylic acid, $C_7H_6O_2$, of Kolbe and Lautemann, and the other appears to be identical with Church's dicresol, C_7H_7O.‡

To obtain stilbene I treated the bitter almond oil of commerce with an equivalent quantity of sodium, and distilled the mixture at a temperature sufficiently high to bring over everything volatile. The distillate was again treated with sodium and fractionally distilled. One portion came over below 200°, and contained volatile liquid hydrocarbons, among which benzol was observed. The fraction distilling between 200° and 244° did not yield any crystals, even when exposed to a freezing mixture of ice and salt. That portion of fluid which distilled between 244° and 265° became nearly solid on cooling. Above 265° the distillate consisted chiefly of crude stilbene. The fluid distilling between 200° and 244° contained carbon 85·3, hydrogen 8·1, oxygen 6·6. It was apparently a mixture, and probably contained a small quantity of stilbene in solution.

The solid substance was dissolved in hot benzol, and on cooling gave a crop of beautiful colourless prismatic crystals, which, when perfectly freed from benzol by exposure for some time to a temperature of 100°, gave the product *a*. The mother liquid, on standing, gave a second crop *b*, which was freed from benzol in the same manner as the first. The third crop *c* was only purified by pressure between folds of filtering paper. The residue, evaporated to dryness and sublimed, gave crop *d*. The melting points were as follows:—

a	113°
b	116°
c	78°
d	100°

The second crop was burned with oxide of copper and oxygen gas, with the annexed result:—

0·2227 gramme of crop *b* gave
0·7642 ,, carbonic anhydride, and
0·1374 ,, water.

Or, per cent.:—

	Experiment.	Calculation, Stilbene.	
Carbon	93·59	93·33 C_{14}	168
Hydrogen	6·85	6·67 H_{12}	12
	100·0		180

Agreeing, therefore, with the formula $C_{14}H_{12}$, which is that of stilbene.

The melting point of the specimen analysed was 116°. Laurent does not give the melting point of stilbene, but merely states that it fuses several degrees above 100°.

The vapour density of stilbene as given by Laurent is 8·4, a number which is entirely incompatible with the formula. Therefore, although I only had a very minute portion (less than two decigrammes) of stilbene left, I resolved to repeat the vapour density determination, feeling sure that even if the experimental result was not so accurate as might be desired, it would still be a sufficient approximation to indicate the true formula of the substance analysed. The experiment was made in an atmosphere of mercury vapour, with the annexed result:—

Excess of weight of balloon	0·1371 gramme.
Temperature of vapour	350°
Temperature of air	17°
Pressure	764 m.m.
Capacity of balloon	95·5 c.c.
Residual air	12·5 c.c.

Experiment.	Calculation.
6·024	6·228

The large amount of residual air, and the smallness of the scale on which the experiment had to be made, make me regard this experiment as one requiring to be repeated. It is, however, quite near enough to the theoretical value to show that the number obtained by Laurent was due to some error of experiment.

It is important to observe that the specimen of stilbene which fused at 116° had its melting point raised to 120° by keeping it for some hours at a temperature of 100°. It is evident, therefore, that the fusing point of stilbene is not lower than 120°.

Recent Analysis of the Montpellier Saline Chalybeate (Kissingen) Spring at Harrogate, by Dr. SHERIDAN MUSPRATT, *M.D. (Hon.), F.R.S. Ed., M.R.I.A., &c.**

As there have been so many strange analyses, some most conflicting, of the water of the above celebrated spring,

* Communicated by the author.

† *Ann. der Chem. und Pharm.* cxxxvii. 92. "Ueber die Einwirkung von Natriumamalgam auf Benzoylwasserstoff in ätherischer Lösung."

‡ *Ibid.* cxxviii. 301.

* Communicated by the author.

I have for some months been engaged with experiments and researches upon it; and feeling that the results elicited are now the true ones, I place them before the readers of your ably conducted journal. In the CHEMICAL NEWS for June 29, of last year, it is stated that this Kissingen spring holds the following:—

Carbonate of baryta	7·657
Carbonate of strontia	2·815

Neither of these earthy carbonates is contained, as such, in the water. The barium exists as a chloride—*i.e.*, in the same form as it does in the "Dr. Muspratt chalybeate, or chloride of iron spring." Annexed is the new analysis, collaterally with that of my friend Dr. Hofmann:—

Carbonic acid	24·17	21·33
Carbide of hydrogen	2·40	2·74
Oxygen	·51	·77
Nitrogen	6·48	5·92
	33·56	30·76

The quantity of chlorine in the gallon was estimated by my assistant, my brother Edmund, five other chemists, and myself, and the mean (by weight and volumetrically) was 596·472 grains per gallon. The total amount of chlorine in June, 1865, was 510·17 grains per gallon; in March, of this year, I found 592·5 grains. From the recent analysis, the water is much stronger in its saline ingredients; besides, it has acquired others (chlorides of barium, &c.) that did not exist in it previously. When the late Mr. West, of Leeds, analysed the water from this spring many years ago (1844?), he gave 20 grains of sulphate of soda in the gallon. If this salt was present then—it could not possibly be there with chloride of barium—it is not now found in any of the strongly impregnated waters of Harrogate, "the queen of northern spas," as justly styled by Dr. Granville. The springs to which Harrogate owes its celebrity exceed in number those of any other place in the kingdom.

College of Chemistry, Liverpool, May 1.

TECHNICAL CHEMISTRY.

Notes on Thallium and Magnesium Alloys, by S. MELLOR, *Esq., Manager of the Magnesium Metal Company.**

IT having been suggested that if an alloy of thallium and magnesium could be easily made into wire it might be found to burn readily and to produce an intense bright green flame, which, from its portability, would be well adapted to some of the purposes for which a green flame is required, some experiments have been made with this end in view.

It was found that thallium alloys most readily with magnesium, and in any proportions. The alloys are very stable, and are easily worked up into wire and ribbon. Alloys containing 5, 10, 15, 20, 25, and 50 per cent. of thallium were prepared. These all burn brightly and steadily, but the flame is smaller and the combustion slower than that of pure magnesium. The flame is cold, and the heat-conducting property of the alloy, compared with magnesium, is sensibly diminished, showing the change in the molecular construction of the metal. The smoke produced in the combustion of these alloys is more dense, and as it curls gracefully away it is seen to be fringed with a rather pretty dark purple tint; but the magnesium light is so very intense that it almost completely masks the thallium flame, so that it is not observable in some of the alloys—indeed, the green light is scarcely recognisable even in an alloy containing 50 per cent. of thallium.

An alloy of 5 per cent. of thallium appears to render magnesium less brittle and more ductile than pure magnesium is usually produced; but the higher alloys of thallium, say those containing 25 and 50 per cent. of thallium, are more oxidisable than pure magnesium.

The metals were put together cold in a closed iron crucible; only a slow heat was required to melt them.

* Communicated by the author.

PHARMACY, TOXICOLOGY, &c.

On Colchicia, by JOHN M. MAISCH.*

THE collection of chemicals in the Philadelphia College of Pharmacy contains a specimen of colchicia prepared by Mr. Carter in 1857; a portion of this was used for the purpose of clearing up the contradictions in the statements of different authors. The substance is a light yellow amorphous powder, possessing a very faint odour and intensely bitter taste, sparingly soluble in ether, but easily soluble in water and alcohol, the aqueous solution being slightly turbid, most likely in consequence of the decomposition of a small portion into resin and colchicein. Heated upon platinum foil, it fuses; at a higher heat, it takes fire and burns without leaving any residue. Placed upon moistened red litmus paper, the blue colour is restored; very faintly reddened litmus becomes blue also by a concentrated aqueous solution. One drop of dilute sulphuric acid dropped from a bottle giving fifty-two drops to the fluid drachm, consequently about one-eighth of a grain HO,SO_3, when mixed with one grain of colchicia, retained its acid reaction. One drop of the acid was mixed with one fluid ounce of distilled water; in five minims of this mixture, equal to about one-seven hundred and seventieth grain HO,SO_3, one-sixteenth grain colchicia was dissolved, and the solution now had a distinct alkaline reaction on slightly reddened litmus paper; but on heating this solution to the boiling point, it had acquired an acid reaction.

The most important tests for recognising the presence of colchicia are its behaviour to dilute acids and also alkalies, by which its solution acquires a yellow colour, and the violet and blue colour which is produced by oxidising agents with dry colchicia. This latter coloration, which changes through various shades finally into yellow, is strikingly beautiful when concentrated sul-

* Abstract of a paper in the *American Journal of Pharmacy*, xxxix. 97.

phuric acid is used and immediately some nitric acid or a fragment of a nitrate is added; strong nitric acid produces it likewise, but it changes more rapidly to yellow. Sulphuric acid with a trace of chromate or bichromate of potassa, or of sesquichloride of iron, or of binoxide of lead, shows the same reaction at the point of contact with colchicia; the liquid itself has a green colour with the first two reagents, owing to their intense yellow colour.

One grain of colchicia was dissolved in one fluid ounce of distilled water, slightly acidulated with muriatic acid; by repeated trials it required 114 drops from this phial to make one fluid drachm; this measure had been carefully gauged with a pipette graduated into $\frac{1}{100}$ c.c. In making the following experiments, a sufficient amount of the reagent was added to enough distilled water to make one fluid ounce, and the solution of colchicia was carefully dropped in until, after stirring, a permanent turbidity was observable. Under these circumstances, it was required of

Mayer's iodohydrargyrate of potassium, 15 drops; turbidity quite distinct.
Sonnenschein's phosphomolybdic acid, 20 drops; turbidity distinct.
Tannic acid, 100 drops; turbidity scarcely observable.

It follows from this that the following amounts of colchicia may be detected by

Mayer's test . .	·01645 grains, or	1 part in	27700 water.†
Sonnenschein's test	·02193 ,,	,,	20778 ,,
Tannic acid . .	·10965 ,,	,,	4156 ,,

Solutions of colchicia in water acidulated with sulphuric and with muriatic acid were evaporated and taree times taken up by water and again evaporated; tne aqueous solutions were finally filtered from the separated resin, and the filtrate slowly evaporated with an excess of carbonate of lead, the residue then treated with strong alcohol and slowly evaporated. Colchicein was obtained in yellowish crystals, which were free from acid and lead. Dissolved in water it still yields precipitates with tannin, phosphomolybdic acid, and iodohydrargyrate of potassium; but neither in solution nor in substance does it produce any reaction on red or blue litmus paper. Rendered faintly alkaline by ammonia, the solution occasions precipitates with the soluble salts of barium, calcium, and lead, which are soluble in dilute nitric acid. Towards acids it behaves similarly to colchicia.

The resinous matter remaining on the filter when colchicein is filtered off was dissolved in alcohol, and the solution evaporated; an amorphous brown-greenish mass was left, in which alcoholic solution has a decided acid reaction. Concentrated nitric acid dissolves it with an evanescent yellow colour; on the addition of sulphuric acid the solution takes place with a purplish brown, rapidly disappearing; pure sulphuric acid dissolves it with a brown colour.

Having looked in vain in every portion of the decomposed colchicia for glucose, or a compound which would reduce an alkaline solution of copper, the observations of Oberlin, Ludwig, and Hübler are confirmed.

Taking all these results together, no doubt colchicia must be looked upon as an alkaloid, the salts of which are soluble in water, but decomposed, with the formation of colchicein, on keeping them in solution as well as on evaporating them. The crystalline mass, obtained by Mr. Carter on evaporating sulphate of colchicia, was undoubtedly colchicein.

† One fluid ounce water = 455·669 grains.

Aschoff and Bley observed already that colchicia combines with bases, and that when it is evaporated with a solution of the carbonate of an alkali, the residue contains no carbonic acid. Hübler makes it probable that colchicein is formed under these circumstances. Colchicia is a very weak base, and colchicein, if it can be regarded as an acid, is certainly a weak one, and resembles the alkaloids in its behaviour to some reagents. If colchicia and colchicein have the same composition, the acid resin formed together with the latter can scarcely be different.

In preparing colchicia the action of alkalies and acids, particularly when heat is applied, must be avoided.

FOREIGN SCIENCE.

(From our own Correspondent.)

Paris, May 15, 1867.

The Academy of Sciences includes in its body four sorts of members—titular, foreign associates, free academicians, and correspondents. According to the spirit which animated its creation under the ancient monarchy, the free academicians were ordinarily high-placed men, or at least men occupying an elevated position in society, well known to be the friends of science and disposed to patronise it. They had all the rights and privileges of titular academicians—that is to say, they took part in all the elections, could form part of all the administrative or other commissions, &c. They did not receive the small stipend attached to the rank of member of the Academy, but they took their share of the presentation tickets. In this primitive state of things, the title of free academician was superior to that of the titular one, and it was ridiculous to ask the first-named to abdicate in favour of the latter. At the time of the re-organisation of the Institute of France and of the five academies which compose it, the democratic spirit which predominated at the discussion of the regulations—at least, as far as concerned the Academy of Sciences—ended by putting the primitive and very legitimate institution of the free academicians in a false position, and in reducing their body to an inferior number, and thus subjecting them to humiliation, though they were always chosen from the first ranks. For example, they are deprived of their votes in the elections of titular and corresponding members, and they cannot take part in any elections except for free members like themselves. In our opinion this inferiority, contradictory in itself, ought to have disappeared long ago, the more so as it keeps up in the Academy an antagonism much to be regretted, and a mutual silent but deep-seated discontent, which has already given rise to violent discussions, and, we are sorry to say, combats with arms less noble and worthy of the members. At this moment the fire is smouldering under their feet, and may burst out as a volcano. Among the ten free academicians, three—Marshal Vaillant, M. Antoine Pussy, Count Jaubert—are present or former Ministers of State. The most ardent advocate in defence of the rights of the corporation is the Count Jaubert, well backed by the most ancient of his colleagues, Baron Sequier, a distinguished amateur mechanical engineer, formerly councillor at the Royal Court of Paris. Marshal Vaillant does not take any visible part in the conflict, but he nevertheless is mixed up in it, perhaps with a sort of disgust at the proscription with which the free academicians are struck, and he hopes, openly, but timidly, to push into the list of the titulars. A most distinguished officer of the French military engineers, universally informed, an ingenious and popular writer, an eminent agriculturist and meteorologist, he had, in the judgment of François Arago, and, we may say, of everybody else, all the talents and qualities for a titular academician; no one could be more fitted to fill a chair actively. It was a good occasion for granting his

request. Not without his high influence the Academy entered into possession of their new chair; if the Marshal had not objected, the Emperor would have, according to the accustomed usage, named by a decree the first titulars, and in the first place Marshal Vaillant. In how many circumstances the Marshal has been the ready and powerful intermediary between the Academy and the executive for the foundation of new prizes, the increase of the value of existing ones, or the concession of scientific missions! He has been advised to resign his position as a free academician, and to be proposed as candidate for the place of titular academician in the section corresponding to his works. He will not do that; he cannot, on account of the respect for those who share the seat with him—a seat awkwardly lessened not in dignity but in rights. He declares that he puts himself solely at the disposal of the Academy, and that, although he will not resign his present chair, he will accept with gratitude the chair of titular academician.

What is wanted more? Can we understand how a body formed of such celebrated scientific men can much longer hesitate in acquitting what we do not fear to call a debt of honour and gratitude? Marshall Vaillant had two votes in the last election, and we have heard them named as unconstitutional. This is a farce, and these two votes must absolutely become unanimity for the election of the Marshal in the Section of Geography and Navigation. Thus, if the Academy of Sciences does not decide upon rendering to the free academicians their primitive rights of participation in all the elections, it ought at least to suppress the derisive term; for it is repugnant to common sense now to have only the mutilated honour of a free academician.

We have not succeeded in ascertaining at all definitely the series of the deliberations and the awards of the juries. We know, however, that in Class 72, Group VII.—sugars and confectionary products—the jury propose to award four gold medals: the first to Prussia, the Zollverein exhibitors, for the *ensemble* of their products, and especially the sugars manufactured directly and ready for immediate delivery for consumption; the second to the Mauritius for the considerable increase in the production and the progress accomplished; the third to M. C. A. Say for the products of his refinery, an excellence demonstrated by the enormous quantity and the extent of his exhibition; the fourth goes to France, considered in the light of its being the mother country of the great industry of sugars. Here, again, the needle-gun carries off the palm, and we are well beaten.

The Society of Encouragement held on Friday, the 10th inst., their second extraordinary meeting. The correspondence, summed up by MM. Tresca and Peligot, presented nothing of any interest.

M. Huzard read, in the name of M. Bells, a very favourable report on the shearing machine of M. de Nabat. For clipping horses and sheep-shearing it has been most successful. We prefer by far the little shearer of M. Cazon, which is held and set in motion by the hand, whilst that of M. Nabat is a real machine, like a knife-grinding one, set in motion by the foot.

M. Dumas read a letter, by which our friend, M. Galibert, in gratitude for the success of his respiratory apparatus, placed at the disposal of the Society of Encouragement the sum of 1000 fr., to be employed in forming a fund for the prize, for the best application of the endosmose of gases, to be awarded in 1868. This is one of the questions put forward in the programme of prizes which are most in relation with Galibert's apparatus. M. Dumas congratulated M. Galibert on his generosity, and tendered him the thanks of the Council.

M. Dumas read a second letter from M. Taborin, one of the oldest manufacturers of files, who, spontaneously on his part, and in thankfulness for his success, took upon himself to hand over 3000 francs towards the prize to be awarded in 1870 for a file-cutting machine. This mark of gratitude to the Society was most warmly applauded, and the noble veteran, much affected, rising to give thanks to M. Dumas and the council, to the great surprise of the auditory, said, "To cut files is hard work, and the Society has done well to appeal to mechanical skill for alleviating it; but the forging of them is worse again, and I beg the Society instantly to found at my expense a second prize of 3000 francs for a machine for forging files." Much moved, in his turn, M. Dumas exclaimed, "Honour to the intelligent and energetic man who commenced his industrial career forty years ago with only two and a half francs in his pocket, who has now founded three vast establishments, and who has arrived at a trade of several million francs with honour and profit."

M. Balard presented, in the name of M. Carré, his new ice-producing machine, of which we have often spoken and given a description in our report of the Academy. The principle of this machine consists of sulphuric acid marking 59° to 65°, circulating in a thin stream, through which passes vapour of water drawn along by a vacuum created pneumatically. The evaporation of this produces the cold. The recipient of the acid is formed of an alloy of lead and antimony in the proportion of 5 to 6 per cent.; it supports without alteration of form a pressure of five or six atmospheres, while the pressure in practice cannot exceed one atmosphere. The copper pump is preserved from the contact of the sulphurous acid, always disengaged by the acid recently introduced, by an arrangement which necessarily and constantly oils the inside surface. The valves are opened mechanically, and cannot get deranged. The apparatus keeps the vacuum for several months; the acid is extracted when it has become diluted to about 52°; the congelation commences generally three or four minutes after the commencement of making the vacuum; if cold water at 3° or 4° C. is required, two minutes suffice, and a little shaking up for some instants restores the air which it has lost. Other substances can be substituted for sulphuric acid (which is, however, the cheapest agent to employ), such as caustic potash or soda, or chloride of calcium, which cause a congelation sufficiently prompt and intense. In the application, M. Carré mentioned the adaptation of the apparatus on board ships and in cellars where the temperature could be indefinitely kept at 5° or 6° C. in all latitudes, also for the refrigeration of apartments.

M. Dumas is of the same opinion as M. Balard, with regard to the success of the new ice-making machine, especially if sulphuric acid can be replaced by other substances more inoffensive; he indicated that oven-dried bran, a powerful absorbent, might be tried, and requested M. Thénard to give his opinion, and to state what advantage agriculture would derive from this mode of producing cold. M. Thénard first called attention to the curious and important fact discovered by milk-women, and of which he cannot find an explanation. If milk, a few minutes after being drawn from the cow, be cooled with very cold rain-water, it keeps fresh for many days, and can be sent to a long distance. Carré's apparatus can advantageously replace the cold water, especially in agricultural distilleries, which employ a good deal of sulphuric acid and keep at the same time a great number of cows.

M. Peligot afterwards gave an account of the process of M. Paris for the fabrication of enamels, of which numerous beautiful specimens were laid before the Society. We will resume this subject further on while speaking of the Exhibition.

M. Peligot also called attention to a quite new fact that he had discovered. It arose from the devitrification of a piece of St. Gobain glass, prepared a long time ago by M. Pelouze; the glass had lost its transparency, but not its density. Placed in a drawer, the piece of glass, supported by one extremity, was found, after some days, by M. Peligot to be curved under its own weight, it having become a malleable glass; the surface was also covered

with efflorescence. Pliny speaks, in his history, of a glass that could be bent and unbent; and the story goes that Richelieu ordered an inventor to be put to death for proposing to divulge a process for making malleable glass.

M. Bouillet, in his name and that of the celebrated M. Christofle, mentions two great improvements made in their electro-metallic manufacture. 1. Round bossed galvano-plastic objects could be obtained more economically by the substitution of electrodes of lead for the insoluble platinum wire electrodes used at first by M. Lenoir, the inventor of the process. 2. A series of pieces in bronze, decorated with inlaid work in silver, platinum, and yellow or green gold, had been obtained by electricity, and which perfectly imitated the charming objects coming from China or Japan. F. Moigno.

PARIS EXHIBITION OF 1867.

(From our Special Correspondent.)

Group V.—Class 44: Chemical and Pharmaceutical Products.

(*Continued from page 236.*)

The glass case of Messrs. John Casthelaz and Co., of Paris, contains a very rich collection of chemical products obtained by newly improved processes, which reflect great credit on the firm. We shall enumerate them rapidly. They decompose daily two tons of nitrate of soda by sulphuric acid to obtain either nitric acid, monohydrated nitric acid of 48° to 50°, or pentahydrated from 36° to 40°. Nearly all these acids are employed on the very spot where they are produced. The monohydrated acid serves to produce the nitrated products of benzol and toluol; the acid at 35° is used to transform arsenious into arsenic acid, phenic acid into trinitro-phenic or picric acid, the bichloride of naphthaline into phthalic acid, &c. They transform daily a ton of benzol into nitrobenzol and aniline, and fabricate, on a very large scale, picric acid, crystallised and fused. The weight of some of the specimens attains one or even two kilogrammes. They have invented also, for purchasers, an apparatus termed *picrometer*, which permits them to verify, without trouble, the purity of the acid delivered. Starting with the fact, noticed by MM. Paris and Ernest Depouilly, that the basic phthalate of sulphate of lime at 300° is changed into benzoate of lime, they make naphthaline serve for the production of benzoic acid. Phthalic acid results from the decomposition of the naphthalic bichloride. Phthalate of ammonia distilled gives phthalimide of lucuine; distilled with powdered quicklime, the phthalimide produces benzonitrile, and benzonitrile distilled with caustic soda gives benzoate of soda, from which chlorhydric acid precipitates benzoic acid. Attacked by nitric acid, the bichloride of naphthaline leads to an oil, and forms binitrated chloride or the binitro-chloroform of M. Berthelot, of which the odour is so penetrating, and the action on the eyes and respiratory organs so terribly deleterious. The small vial of this oil which figures in the above-named glass case contains enough to burn the eyes of thousands of visitors. Near it we see the picrates of baryta, iron, lead, and mercury; chloroxynaphthalates of baryta, iron, zinc, nickel, and copper; with the bichromate of potash aniline violets, the soluble garnet colour, isopurpicrate of potash, a fulminating substance which must be kept wetted with water, the product of the reaction of cyanide of potassium on picric acid, which dyes wool in the richest colours with a saving of 25 per cent.

The pure and crystallised products from the laboratory of Messrs. Coblentz Brothers — phenotoluol, azobenzol, nitranilines, binitrobenzol, binitrotoluol, toluyldiamine, and paraniline—do them the highest honour. They are eminently skilful in transforming into colouring matters the direct products of coal tar. They exhibit an enormous block of nitrotoluol admirably well crystallised, of a pale yellow colour, and nearly free from nitrobenzol. They have discovered a very cheap process for transforming nitrobenzol into aniline, and nitrotoluol into toluidine. They take cast-iron turnings, roughly ground to powder, cover them with a layer of metallic copper, by plunging them in a solution of sulphate of copper. These galvanised turnings are then placed along with nearly an equal quantity of non-galvanised turnings, and surrounded by a sufficient quantity of water. Nitrobenzol or nitrotoluol is then added, and a galvanic action takes place in the liquid. The water is decomposed, and the hydrogen makes the nitrate body pass into the state of aniline or toluidine, which is then rectified and rendered pure. By treating the residues with sulphuric acid, the copper is dissolved, and can serve for another operation.

A magnificent and curious experiment will be made in a few days in the middle of the Exhibition, in the portion allotted to M. Flaud, one of the constructors admitted to furnish motive power for the gallery of machines. The experiment is imagined and organised by M. Henry Giffard, the well-known inventor of the injector; but it is to be produced under the name of Mr. Young, formerly the companion of M. Giffard in his steam essay of aërial navigation. It will consist of an anchored balloon, which will rise with twenty or twenty-five persons to a height of about a hundred metres. It will remain some time in the air, and then descend, to ascend again with a fresh party, and so on all day long. The problem of captive aërostation is, it is well known, one of the most difficult of physical mechanics. Arago said it was almost impossible. M. Giffard solves the question on the most rational side, and he will succeed. His balloon is a perfect sphere 21 metres in diameter, formed of two very fine and close tissues stuck together with several coats of black india-rubber American varnish, coated also with linseed drying oil to prevent all osmose or diffusion. This cloth is sufficiently impermeable to hydrogen to keep it in for a time sufficient for prolonged experiments, even for a whole day. The dimensions of the balloon are calculated so as to assure an ascensional power in such a manner that the horizontal component of the wind will only produce a slight deviation in the vertical direction of the cable holding the balloon. Upon this depends all the successful solution of M. Giffard, and it is certain that the angle of deviation will never exceed 40°. The cable unrolls and rolls up on a drum-wheel very solidly fixed. The hydrogen for the balloon will be temporarily procured by the ordinary process—iron and sulphuric acid; but in a few weeks it will be obtained by the decomposition of water by red-hot charcoal, at a price less than 15 c. the cubic metre. Oxygen of M. Tessié de Mothay at 50 c., and Giffard's hydrogen at 15 c. the cubic metre! What a fortunate combination this will make for the use of many industries!

PROCEEDINGS OF SOCIETIES.

MANCHESTER LITERARY AND PHILOSOPHICAL SOCIETY.

Ordinary Meeting, April 16, 1867.

Edward Schunck, *Ph.D., F.R.S., &c., President, in the Chair.*

Mr. Henry Charles Beasley was elected an ordinary member of the Society.

"*On a New Form of the Dynamic Method for Measuring the Magnetic Dip*," by Sir William Thomson, M.A., D.C.L., F.R.S., &c., Honorary Member of the Society.

Seven years ago an apparatus was constructed for the natural philosophy class of the University of Glasgow, for illustrating the induction of electric currents by the motion of a conductor across the lines of terrestrial magnetic force. This instrument consisted of a large circular coil of many

turns of fine copper wire, made to rotate by wheel work about an axis, which can be set to positions inclined at all angles to the vertical. A fixed circle parallel to the plane containing these positions, measured the angles between them. The ends of the coil were connected with fixed electrodes, so adjusted as to reverse the connexions every time the plane of the coil passes through the position perpendicular to that plane. When in use, the instrument should be set as nearly as may be in the magnetic meridian. The fixed electrodes being joined to the two ends of a coil of a delicate galvanometer, a large deflection is observed when the axis of rotation forms any considerable angle with the line of magnetic dip. On first trying the instrument I perceived that its sensibility was such as to promise an extremely sensitive means for measuring the dip. Accordingly, soon after I had a small and more portable instrument constructed for this special purpose; but up to this time I had not given it any sufficient trial. On the occasion of a recent visit, Dr. Joule assisted at some experiments with this instrument. The results have convinced us both that it will be quite practicable to improve it so that it may serve for a determination of the dip within a minute of angle. I hope, accordingly, before long to be able to communicate some decisive results to the Society, and to describe a convenient instrument which may be practically useful for the observation of this element.

"*Observations on the Alteration of the Freezing Point in Thermometers*," by Dr. J. P. Joule, F.R.S., V.P.

Having had in my possession, and in frequent use, for nearly a quarter of a century, two thermometers, of which I have from time to time taken the freezing points, I think the results may offer some interest to the Society. Both thermometers are graduated on the stem, and are, I believe, the first in this country which were accurately calibrated. Thirteen divisions of one of them correspond to one degree Fahrenheit. It was made by Mr. Dancer, in the winter of 1843-44. My first observation of its freezing point was made in April, 1844. Calling this zero, my successive observations have given

0	April, 1844.
5·5	February, 1846.
6·6	January, 1848.
6·9	April, 1848.
8·8	February, 1853.
9·5	April, 1856.
11·1	December, 1860.
11·8	March, 1867.

The total rise has been, therefore, ·91 of a degree Fahrenheit. The other thermometer is not so sensitive, having less than four divisions to the degree. The total rise of its freezing point has been only ·6 of a degree; but this is probably owing to the time which elapsed between its construction and the first observation being rather greater than in the case of the other thermometer. The rise of the two thermometers has been almost identical during the last nineteen years.

"*On the Casting, Grinding, and Polishing of Specula for Reflecting Telescopes, Part IV.*;" by James Nasmyth, Esq., C.E., Corresponding Member of the Society.

In this part of his paper the author gives detailed descriptions, illustrated by diagrams, of his methods of mounting the specula of reflecting telescopes, and of testing the figure of the great speculum; he also offers some very useful remarks on the general management of Newtonian reflecting telescopes, and on the atmospherical circumstances which affect their performance.

PHOTOGRAPHICAL SECTION.

April 9, 1867.

J. Baxendell, *F.R.A.S., Vice-President of the Section, in the Chair.*

Mr. Brothers read the following "*Note on Photography in* 1787."

It is generally supposed that the earlier attempts to use nitrate of silver for producing pictures of lace, leaves, and other objects on white leather or paper were made by Wedgewood and Davy about the year 1802; but it will appear from the following extract that at least fifteen years earlier than the date named, and within ten years of the time when Scheele investigated the subject of the action of light on the salts of silver, the possibility of utilising the action of light was known. The title of the book from which the extract is taken is "Rational Recreations in Natural Philosophy," &c., by W. Hooper, M.D., 1787; and the paragraph is headed "How to print letters by sunlight."

"Dissolve chalk in aqua fortis to the consistence of milk, and add to that a strong dissolution of silver. Keep this liquor in a glass decanter well stopped, then cut out from a paper the letters you would have appear and paste the paper on the decanter, which you are to place in the sun in such a manner that its rays may pass through the places cut out of the paper and fall on the surface of the liquor. The part of the glass through which the rays pass will turn black, while that under the paper will remain white. You must observe not to move the bottle during the time of the operation."

Mr. Coote exhibited some snow scenes, the negatives of which were taken on collodio-albumen plates. Some of these beautiful views were slightly defective in the high lights, a number of vein-like markings appearing in the sky and foreground.

Mr. Wardley stated that these defects were entirely caused in the development, and had no connexion with the character of the collodion used, or with the preparation of the plate. He considered that the imperfections were produced entirely by the repellent or nonmiscible nature of the solutions, containing acids and salts, used in development, acetic acid being one of the chief causes of the defects. Another source of the evil may be a low temperature and the developing solution being allowed to rest, even for a moment, on the plate. Such defects may be produced in abundance on any kind of dry plate if the developing solution is allowed to rest.

ACADEMY OF SCIENCES.

May 13, 1867.

(From our Special Correspondent.)

Dr. Nelaton begged the Academy to inscribe his name among the list of candidates for the vacant chair in the medical and surgical section, by the death of M. Jobert de Lamballe. Is he not rather late in the field—when, during all his life, he was no more interested in the Academy than if it never existed; and when he never made his appearance but once, to read a work made in collaboration with a young recruit? He must have depended upon the little respect paid by the Academy, sometimes, to itself, to offer himself as a candidate in such an unprepared manner. For my part, I shall not give my vote to M. Nelaton, first-rate surgeon though he be among us.

M. Boussingault communicated a new series of researches relative to the deleterious influence exerted by the vapour of mercury on the vitality of plants. He has repeated and modified the very curious experiments made by some Dutch *savants* in 1797. They placed under a bell glass a plant, with a small vessel containing mercury, and they found that, at the end of a few days, or even a few hours, the leaves of the plant were spotted and blackened, and that it ultimately perished. But when they fixed a small piece of sulphur on the inside surface of the bell glass, the deleterious action of the mercury ceased, and the plant remained healthy. It was not difficult for M. Boussingault to assure himself, by a series of careful observations, that the mercurial vapours had a sort of elective affinity for the sulphur—that sulphuret of mercury

was formed, which is inoffensive. M. Boussingault has varied his experiments relative to the action of vapours on plants and the precious metals, silver and gold. He has measured their tension, and appreciated their action on the colours and weight, &c. M. Regnault thinks that the best reagent against the vapours of mercury is an iodised daguerreotype plate ready to be coated and exposed to the light. M. Boussingault maintains that the sensibility of the plates is nothing as compared with that of plants.

M. Pictie, of Geneva, was then elected as member of the Section of Anatomy and Physiology, by forty-two votes against one, given to M. Sace, of Neufchatel.

M. Becquerel, the elder, communicated his series of experiments on the influence of the capillary action of surfaces upon decomposition and chemical combination. He takes a tube with two branches reversed, and makes in it a fissure, the width of which is infinitely small. He pours therein a solution of nitrate of copper, and has found that no liquid passes by the fissure; but when placed in a vessel containing liquid protosulphuret of sodium, an electrical action takes place, and decomposition and recomposition ensue, manifested by the crystals which appear on both sides of the fissure. M. Becquerel has demonstrated the new and curious phenomenon that the capillarity of the fissure has a real influence on the nature of the products of the decomposition; that the salts or the crystallisations are not always those indicated by theory; that the double decomposition often goes to the extent of reduction of the metal.

M. Elie de Beaumont presented, in the name of M. Civiale, an immense collection of urinary calculi, arranged according to their form and structure, composition, &c. He read a long note, giving details of each group.

M. Ch. Sainte-Claire Deville recounted his studies "*On the Periodical Variations of Temperature.*"

The author has established, in one of his former memoirs, that there exists a certain depending connexion in the movement of the mean temperature of four days, placed on the ecliptic at an angle of 90° one from the other, for the four months, opposed two by two, of February, May, August, and November, which contain the critical days, known by the ancients under the name of the *three saints of ice* (May 11, 12, 13), and the *summer of Saint Martin* (November 11). In this new work he shows that the fact is general, and that this connexion or mutual dependence of the four opposite days exists during the whole of the year; whether we take into consideration a considerable cycle —110 years at Berlin, 90 years at Vienna, 50 at London, 40 at Prague and Edinburgh, 30 at Brussels, 24 at Toulouse, 21 at Paris—or that we take in this point of view an isolated year (1864) on several European stations.

The former, depending upon the same data, establishes, in fine, that this connexion is evident also when we combine twelve by twelve the days separated one from the other by 30° of the ecliptic.

The latter phenomenon constitutes the *meteorological month*, as the *season* was established by the consideration of the quadruple days.

M. Marié-Davy presented his ninth memoir "*On the Mechanical Theory of Electricity.*" The *résumé* that we shall shortly publish is a sort of synthesis of the principal phenomena of nature. These are his conclusions:—In a ray of light the vibrations are not in the direction of the wave. In a hot substance, in which μ varies symmetrically all round each material centre, the vibrations take place generally in the same manner on the three axes. In the circuit in activity the electric vibration takes place in the direction of the propagation of the current, and the *vis viva* set at liberty by the chemical action passes along that channel. But light, heat, and electricity have the same *vis viva*, having the same mechanical equivalent.

In this hypothesis of the vibrations, the positive electricity is ether condensed in excess; negative electricity is ether in deficiency. It is a long time ago that we sustained this theory, on which we made a memoir presented to the Academy in 1845. Baron Sequier, in the name of M. Stamm, of Milan, communicated the plan of an association between a horse and a steam motor, inspired by a lecture that he gave last year before the Academy, and in which he drew such a clear comparison between inanimate motors and animate ones working by their own will. M. Stamm, in his vehicle with a steam engine commanded by a horse, has so disposed it that the horse gears the machinery when in motion, and ungears it when he stops; so that he arranges the valves in a manner that, when backing, the steam is reversed, and the intelligence which the machinery wants is supplied by the horse.

NOTICES OF BOOKS.

On the Poisons of the Spreading Diseases. By B. W. Richardson, M.A., M.D., F.R.S. London: John Churchill and Sons, New Burlington Street. 1867.

This reprint of the famous lecture delivered at the Leamington Congress last year, will give some satisfaction, and almost as much disappointment. The satisfaction will be derivable from the many forcible truths and collection of facts, the disappointment caused by their admixture with so much that is mere statement, sometimes almost dogmatic.

Every reader of the book will find this to be a difficulty, for it will be necessary for him to winnow, we will not say the grain from the chaff, but the more healthy corn from the other grains mixed with it.

Although opposed from principle to the practice of ladies attending sanitary congresses and interesting themselves in the details of sewage, we find from the present case that fewer evils than we supposed were without an attending good; for the reflection that the Congress would be of a miscellaneous character, "at which perhaps ladies might be present as well as gentlemen," has been the cause of the selection of the subject of this paper—a paper we honestly think of very great value in much of its substance.

The form that we should like to see this valuable matter assume, would be that of detailed experiments given, and after this the author's deductions from them. The one would remain as valuable staple matter of reference; as regards the latter, a verdict might be given by every reader. There is no doubt that Dr. Richardson has found entirely satisfactory evidence of everything that he asserts; but every thoughtful reader must decline to record a similar conviction for himself in the absence of the evidence.

We have fifteen diseases given arbitrarily as those produced by *organic* poisons, organic being used in a sense of its own. Thus strychnine would not be an organic poison; it is not asserted, however, that it is an inorganic one. In this list small-pox appears as produced by organic poison, boil and carbuncle with infectious ophthalmia (*Ophthal. Egyptorum?*), but chicken-pox, cow-pox, dysentery, are excluded. Typhus appears in the list, and very strong evidence has been tendered of the connexion of dysentery with typhus, and cases, with no apparent fallacy, have been recorded of epidemic dysentery brought from India on board ship causing a typhus outbreak in port by direct infection. Such facts ought not to be ignored in a critical examination of which every step is attended with difficulty. And thus on almost every page the eye is arrested by some very knotty question comfortably disposed of. This renders a detailed criticism a work of almost indefinite length.

To choose a few sentences at random. "Each poison has a specific property always bringing out the same disease through countless ages. All are destroyed by oxidising agents. . . . Exposure to nitrous acid has the same

kind of effect; exposure to sulphurous acid likewise produces destruction."- "Common sulphur preserves them very well; the poison of hospital fever I have been able to preserve for months by this means." (Query: What means?) "The poisons will all dry solid. There is no exception to this rule." (Query: Who has examined this?) "Sulphur, creasote, and arsenic hold these organic poisons in perfect steadiness; they preserve their active properties."

All these quotations require support from experiments, original or otherwise, for any judgment to be formed. Again, "There is reason to believe that in the decomposition of sewage water cholera poison may be developed." These quotations are all from two or three consecutive pages, and are accompanied by many others of the kind.

Is our demand for a detail of experiments then unjustifiable? If these are not forthcoming, England must yield the palm to America; for Dr. Richardson quotes some experiments that are convincing.

"During the great American struggle, Dr. Salisbury observed that a large number of men rose one morning with symptoms of measles. . . . The men attributed their illness to the straw upon which they lay. . . . Dr. Salisbury removed from the straw certain portions of fungus; he had the courage to inoculate himself with the fungus, and he thus produced measles. He then inoculated *his own wife*, and then *a mother and four children*, then a mother and two children, and produced in all the same disease." We must leave the reader to judge of the feelings of the ladies present at this great sanitary congress.

CONTEMPORARY SCIENTIFIC PRESS.

[Under this heading it is intended to give the titles of all the chemical papers which are published in the principal scientific periodicals of the Continent. Articles which are merely reprints or abstracts of papers already noticed will be omitted. Abstracts of the more important papers here announced will appear in future numbers of the Chemical News.]

Poggendorff's Annalen. February 11, 1867.

C. G. Junge: "*Remarks on the Diffusion of Steam through Dry Atmospheric Air and on some other Hygroscopic Phenomena.*"—E. Zettnow: "*Researches on Wolfram and its Compounds.*"—P. Kremers "*On the relative Volume of Compounds of the First Degree.*"—J. Muller "*On the Focal Length of Lenses;*" "*On the Fluorescence Spectrum of the Electric Light.*"—W. Holtz "*On the Production of the Electric Spark in Glass, with especial Reference to the Electrical Machine;*" "*On the Theory of the Construction of Electrical Induction Machines.*"—A. Brezina "*On the Use of the Stauroscope.*"—F. Lindig: "*A Reply to H. Schiff's Paper on Supersaturated Solutions.*"—C. Rammelsberg "*On the Composition of Franklinite.*"—Arndt "*On Nägeli and Schwendener's Method of Calculating the Magnifying Power of Microscopes.*"—W. Schmidt "*On a new Metallic Thermometer.*"

Journal des Fabricants de Papier. February 15, 1867.

E. Bourdilliat "*On Testing the Chemical Products used in Paper Making (Continuation).*"—J. Mauslay "*On the Preparation of Chlorine.*"

NOTICES OF PATENTS.

Communicated by Mr. Vaughan, F.C.S., Patent Agent, 54, Chancery Lane, W. C.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

659. W. R. Lake, Southampton Buildings, Chancery Lane, "An improved mode of coating paper and other materials with fluid substances, solutions, and compounds for photographic and other purposes." A communication from J. C. Crossman, Boston, Mass., U.S.A.—Petition recorded March 8, 1867.

1042. W. Henderson, Glasgow, "Improvements in oxidising minerals, ores, and metals; in reducing oxides of metals; in separating certain metals from each other; in kilns, furnaces, or other apparatus for these purposes; and in the treatment of the products obtained therefrom."—April 6, 1867.

1087. W. H. Dawes, West Bromwich, Stafford, "An improvement or improvements in the manufacture of iron."

1091. C. Wilmet, Brussels, "An accelerated tanning by means of new processes and apparatus."—April 12, 1867.

1099. J. Aitken, Tottington Higher End, Lancashire, "Certain improvements in apparatus employed in the process of refining sugar."

Notices to Proceed.

3307. C. E. Brooman, Fleet Street, "Improvements in the preparation and application of certain fatty bodies." A communication from M. P. Javal and E. P. Javal, Paris.—Petition recorded December 15, 1866.

22. W. Knaggs, Euston Grove, Euston Square, Middlesex, "Improvements in apparatus for evaporating and boiling saccharine liquors."—January 3, 1867.

47. W. Way, M.D., Eliot Place, Blackheath, Kent, "Improvements in preparing phosphatic minerals for use as manure." Partly a communication from C. Henwood, Sombrero, West Indies.—January 7, 1867.

250. E. V. L. Ebersburg, Knightsbridge, Middlesex, "A new or improved article of food for infants and invalids." Partly a communication from Baron J. von Liebig, Munich, Bavaria, Germany.—January 30, 1867.

819. J. Greenshields, Glasgow, N.B., "An improved compound or combination of materials to be used for the production of illuminating gas."—March 21, 1867.

CORRESPONDENCE.

The Chemical Society.

To the Editor of the Chemical News.

Sir,—Your leading article in the Chemical News of Saturday last interested me. I have long been expecting to see evil effects arise from the admission of so many persons into the Chemical Society who are manifestly unworthy of that honour. I mean persons who simply pay the fees, and do not promote chemistry either by original communications, or in any other way worthy of the title F.C.S. The followng circumstance may perhaps interest you, as it relates to this subject:—A junior partner in a manufacturing firm was admitted into the Chemical Society; on being asked what chemical investigations he had made to entitle him to that honour, he replied that other persons made investigations besides those who published them, meaning thereby that he had made chemical investigations, but did not publish them. The objects of the Chemical Society are defined to be "the promotion of chemistry, and of those branches of science immediately connected with it, by the reading, discussion, and subsequent publication of original communications." The admission, therefore, into the Society of persons whose practice (as in the above instance) is to monopolise chemical knowledge, and keep it secret for their own personal advantage only, is contrary to the objects for which the Society exists; it is also conferring an honour upon persons who do not adequately deserve it. Further, the admission of persons whose only object is to promote their trades, and the getting of money by them (however worthy those objects are in themselves), is unjust towards those members who, at considerable sacrifice and much self-denial, aid in the extension of chemical knowledge. I am, &c.

F.R.S., F.C.S.

Caramel Colours.

To the Editor of the Chemical News.

Sir,—Under the "Notes and Queries" in your valuable paper (No. 387), I happen to find one concerning caramel. Perhaps the following may be of use to your correspondent.

The manufacture of caramel (coffee finings, as it is often termed in London) is kept a secret on this account, that neither coffee-roasters, nor dealers in groceries, nor brewers, may have, or at least are presumed not to have, any in their possession—the Excise prohibiting it. Here in London it is made by roasting sugar of coarse description in cylinders similar to those used for roasting coffee, chicory, and cocoa; this yields a very inferior preparation both for colouring as well as for admixture with coffee. So prepared it contains assamar and other pyrogenetic products which are very bitter. On the Continent apples of inferior description are treated as described, yielding a product superior to that obtained from sugar. Sugar, however, is the only fit material to prepare caramel, and for this purpose the sugar is best heated in capacious roomy vessels made of copper (in Vienna copper lined with silver is preferred), the vessel containing the sugar being placed in an oil bath* containing a thermometer to indicate the temperature. The latter must not be below 410° nor above 428° Fahr. The heating of the sugar is continued as long as aqueous vapours are given off. The crude caramel so obtained is best purified by being placed upon a parchment paper dialyser, which is placed on water. The undecomposed sugar and intermediate compounds are thus got rid of; they dissolve out with facility, and what remains on the filter is, weight for weight, five times as strong in colouring matter as the crude caramel. While the sugar is being exposed to heat it is preferable to stir it with a spatula.

Another mode of obtaining a pure caramel, free from bitter produce (assamar and the like), is to heat the sugar as above, and to treat the powdered caramel with alcohol (pure methylated spirits), to digest it for three to four hours therewith, and repeat this till all bitter taste is gone. An aqueous solution containing 10 per cent. of purified caramel is gummy, and forms a jelly. When a solution of caramel in water is evaporated *in vacuo* (small vacuum pan as used in sugar refineries), it dries up to a black shining mass, freely soluble again in water, hot or cold; but if the solution is evaporated on a waterbath to dryness in contact with air, the whole mass becomes insoluble in water either hot or cold.

A very small proportion of caramel gives to a large bulk of water the dark brown tinge known as sepia. An impure but pretty strong solution of crude caramel (*i.e.*, not purified by dialysis or alcohol—hence the term impure for the solution) is sold in London under the name of Coffeena in small bottles at 1s. per bottle, to be had in many oil and colour shops in the metropolis; it is used in teaspoonfuls to improve coffee, dispensing with chicory.

I am, &c. A. Adriani.

London, May 7.

P.S.—Treacle is not very manageable to use for the making of caramel. The sugars should be first dried at 212° Fahr. On the Continent dry glucose is sometimes used instead of cane or beetroot sugar for the purpose of making caramel.

Obituary.—It is with regret that we announce the death of Mr. Hippolyte Baillière, the well-known scientific publisher, which took place on Saturday last at his residence, 219, Regent Street. Mr. Baillière's illness has been long and painful, and for some time past his sons have taken a very active part in the practical management of the business. The late Mr. Baillière's energy and talents have caused his name to be known and respected in many of the capitals of Europe and America.

* A mixture of tin and lead is sometimes used, just made so as to remain fluid at from 412° to 430° Fahr.; some bismuth is added.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Aromatic Monamines give rise to Acids richer in Carbon.—A. W. Hofmann. The principal product obtained by distilling one molecule of oxalic acid with two molecules of aniline is phenylformamide, but secondary actions give rise in addition to carbonic dioxide; from the proportions one molecule of oxalic acid and one molecule of aniline, a crude product was distilled containing cyanhydric acid; heated with concentrated chlorhydric acid, and distilled, this crude distillate gave off with the steam an oily body of aromatic odour, which, when boiled with solution of soda, partly dissolved with disengagement of ammonia (resulting from decomposition of diphenylamine); the addition of chlorhydric acid to the alkaline solution produced a precipitate of benzoic acid, the argentic salt analysed, showing that the oily liquid with aromatic odour contained benzonitrile. This body evidently results from splitting of phenylformamide into water and benzonitrile.

The production in an analogous reaction of toluylic acid from toluidine, and of a superbly crystalline acid, $C_{11}H_8O_2$, from naphthylamine, proves the generality of the reaction. —(*Comptes R.* lxiv. 387.)

Reactions, General Conditions of.—M. Berthelot considers that a chemical reaction which is capable of setting free a notable quantity of heat will necessarily and directly occur whenever the following conditions exist:—1. The reaction is one which reaches its limit within a very short time from its commencement; this condition is fundamental. 2. The reaction is one which begins without foreign aid at the temperature of the commencement of the experiment; reactions excluded by this condition act in conformity with the principle enunciated, if they are caused to set in, either by raising the temperature or by other means. 3. The parent substances and the products possess similar functions. He is of opinion that the inverse reactions of iodhydric acid and argentic chloride might be foreseen from the basis of this general principle, and that the analogous action of iodhydric acid on potassic chloride, which he has experimentally verified, is a further proof of the correctness of his view.—(*Comptes R.* lxiv. 413.)

Glass.—L. Clemandot. A sample of glass was made from silica and soda, free from lime, the silica being greatly in excess; after fusion at a very high temperature, and while fusing, a portion was taken out; this portion has remained perfectly unaltered; the remainder, after slow cooling in the crucible, became devitrified. Excess in the proportion of any one ingredient is likely to render glass devitrifiable. The most stable glass is that one which is most complex in composition—that is, which contains the greatest number of bases.—(*Comptes R.* lxiv. 415.)

Colours from Coal-tar (C = 6).—De Laire, Girard, and Chapoteaut. If, in preparing violaniline (3 molecules of aniline conjoined with elimination of H_6), aniline containing toluidine be used, the product is contaminated with a small quantity of rosaniline, and a larger proportion of mauvaniline—

$$\left.\begin{matrix} C_{12}H_4,H \\ C_{12}H_4,H \\ C_{14}H_4,H \end{matrix}\right\} N_3,HO,$$

a base possessing remarkable tinctorial properties. Its formula is substantiated—1st. By its formation by appropriate oxidation of a mixture of aniline and toluidine containing a greater proportion of the former. 2nd. By simultaneous formation of water. 3rd. By the replacement in its molecule of H_3 by methyl, ethyl, phenyl. 4th. By its decomposition on distillation into the primary and secondary monamines of the phenylic and toluylic radicals. It is derived from two molecules of aniline and one molecule of toluidine, H_6 being eliminated; it is crystallisable; retains HO even after several hours' exposure to 120—130°, but loses it at a higher temperature; it is

soluble in ether, benzol, and alcohol; insoluble in cold, sparingly so in boiling water; it forms crystallisable salts with acids; the acetate and chlorhydrate are especially fine bodies; the salts are slightly soluble in cold water, rather soluble in boiling water. Triphenylomauvaniline is obtained by acting upon mauvaniline with aniline; it is a crystallisable base, soluble in ether and alcohol, insoluble in water; its salts form splendid blue dyes.

Violaniline, mauvaniline, rosaniline, and chrysotoluidine (derived from the conjunction of three molecules of toluidine, H_6 being eliminated) are the first four consecutive terms of a series having a common difference C_2H_2.—(*Comptes R.* lxiv. 416.)

Retene: its Constitution (C = 6).—M. Berthelot. Retene $C_{36}H_{18}$ is distinguishable from naphthalene, which it resembles in aspect by its having no odour, by its lesser solubility in alcohol, and by its melting at 95°; it boils at about 400°; the vapour, mixed with hydrogen and passed through a red-hot tube, decomposes, producing large quantities of anthracene, carbon, acetylene, and some gaseous hydrocarbons, one of which is absorbed by monohydrated sulphuric acid. Yielding, under these conditions, anthracene, from which it differs by $4C_2H_2$, it cannot be derived from benzol, although its formula is triple that of benzol, but it might be derived from benzol and a hydrocarbon such as ethylene or formene, capable of supplying the acetylene necessary for the production of anthracene, its lower homologue. Attempts to obtain it from cumol in a reaction similar to that which gives anthracene from toluol have not been successful. The first members of the homologous series commencing with anthracene, and including retene, will probably be found among the solid hydrocarbons which crystallise immediately after naphthalene in the heavy oil of coal-tar.—(*Bull. Soc. Chim. Paris*, 1867, 231.)

Xylol, Chloro-derivatives of (C = 12).—C. Lauth and E. Grimaux. Xylol (distilling entirely between 137° and 139°) vapour and chlorine gave a liquid from which a fraction collected between 190—195° precipitated cold argentic nitrate solution; boiled with argentic acetate, a liquid of agreeable odour, probably tolylic acetate, was formed; boiled with plumbic nitrate solution, a liquid having an odour resembling bitter almond oil, combining with sodic disulphite, and boiling at 200°, was produced, evidently C_8H_8O tolylic aldehyde. Therefore, in the first-mentioned reaction a change occurs analogous to that by which benzylic chloride is produced from toluol, and the chlorxylol obtained should be represented by

$$C_6H_4 \begin{cases} CH_2Cl \\ CH_3 \end{cases}$$

The fractions distilling between 230—260° contained $C_8H_8Cl_2$, a crystalline body, but in smaller quantity than was necessary for the study of its reactions; it melts at 100°. It is proposed to extend this reaction to trimethylphenyl, cumol from coal-tar, the alcohol $C_9H_{12}O$ being at present unknown.—(*Bull. Soc. Chim. Paris*, 1867, 233.)

Alizarin.—C. Koechlin. The colouring matter from madder, after sublimation or exposure to 280°, no longer gives the tints sought by dyers; a yellow tint is wanting, in searching for which the author is engaged with Schützenberger.—(*Bull. Soc. Chim. Paris*, 1867, 235.)

Benzolsulphurous Acid (C = 12).—R. Otto and H. Ostrop. Benzolsulphurous chloride, $C_6H_5ClSO_2$, most carefully dried, was diluted with ether perfectly free from alcohol and water; sodium amalgam was added by small portions till a sample of the fluid, after expulsion of the ether, dissolved in water; the ether was then expelled, and a small quantity of water was added; the aqueous solution was separated from an oily body, and mixed with chlorhydric acid; the crystals which formed were recrystallised from hot water, and about two-thirds the theoretical quantity of benzolsulphurous acid was obtained. Its properties were the same as described by its discoverer, Kalle, who made it from zincic ethide and benzolsulphurous chloride. With fuming nitric acid benzolsulphurous acid gave $C_{18}H_{16}N_2S_3O_6$, for the unravelling of the constitution of which material was wanting; nitrobenzolsulphuric acid $C_6H_5(NO_2)SO_3$, was also formed. With bromine, benzolsulphurous bromide was produced, C_6H_5,SO_2,Br, and not brombenzolsulphurous acid, C_6H_4Br,SO_2,H, for ammonia gives with it an amide, and not ammonic brombenzolsulphite. With phosphoric pentachloride, benzolsulphurous chloride, and a body probably $C_{12}H_{10}S_2O_3$, separated from the former by dilute solution of potash, were obtained. The oily body formed in the first reaction, and toluol- and xylol-sulphurous acids, will form the subjects of future communications.—(*Ann. Chem. Pharm.* cxli. 365.)

Valerylene, Polymers of (C = 12).—E. Reboul. Concentrated sulphuric acid acts violently on valerylene; no conjugated acid is formed. A fraction of the product between 175—177° was divalerylenic hydrate, $2C_5H_8,H_2O$. The fraction between 265—275°, sp. gr. 0·862, at 15°, was trivalerylene, $(C_5H_8)_3$. The distillate between 280—350°, in which interval the thermometer rises continuously, as also the residue, which, on cooling, solidified to a semi-transparent mass, is a mixture of polymers of different degrees of condensation. Sulphuric acid diluted with one or one-third volume of water produces the same results, but more slowly, and consequently with less violence.—(*Comptes R.* lxiv. 419.)

MISCELLANEOUS.

Conversazione at the Pharmaceutical Society.—The annual gathering of the members of this Society and their friends took place on the evening of Tuesday last. The attendance was very numerous, and included several visitors distinguished in various branches of science. During the evening Mr. Baines gave a descriptive lecture on his geographical and ethnological explorations in the interior of Africa, profusely illustrated with photographs and transparencies, which were projected on a screen from a magic lantern. The objects of interest to chemists were very numerous, and amongst other novelties included large masses of fused and forged platinum, magnesium in various forms, and pure hydrate of sodium, by Messrs. Johnson and Matthey; Mr. Beane's valuable ozone generator exhibited at work, as used for the decolorisation of sugar, by Mr. Ladd; Professor Wheatstone's magneto-electric machine; specimens of the new porcelain standard yard and metre, as adopted by the International Association for obtaining a uniform decimal system of measures, weights, and coins, exhibited by Mr. Casella; and a new form of gas-engine, and a new hot-air engine. These last two are sufficiently interesting to deserve a more extended notice. The gas-engine is the invention of M. P. Hugon, and is the first we have seen that requires no electricity. This engine may be worked the whole day without any supervision whatever, and requires nothing but turning on and lighting the gas to set it in full work. When once started it may be locked up and left going day and night without stopping. There is so little danger from its use that its presence does not affect insurance. The expense of the power is said to be about one halfpenny per man per hour, and, used in this form, the employer possesses the advantage of discharging the labour at any moment, and of only paying for it whilst actually required.

The hot-air engine is based upon the fact, long known to scientific engineers, that the most economical mode of obtaining power from heat is by its direct application to the expansion of air, or other permanent gases, rather than by that of steam or any other vapour. The hot-air engine now described differs from the so-called "caloric engines" in several essential particulars as to its construction, so that it is free from those defects which have hitherto pre-

vented the practical carrying out of the caloric theory. In this engine the motive power, instead of being derived from the expansion of air heated in a separate generator, as in former engines, is produced by the expansion of air heated by contact with the fuel itself, and, in addition to this source of the power, by the action of the expansive force of the gaseous products of the combustion of the fuel, which heretofore have been permitted to escape into the chimney without being in any way utilised in the production of power. This result is accomplished by placing the fuel in a grate which can be hermetically closed, and forcing the air required for combustion into it by means of an air-pump worked by the engine itself, so that no part of the heated air of the gases produced by the combustion of the fuel can escape without passing through the cylinder, and there doing duty in the production of force. It is obvious that by such an arrangement the employment of separate iron generators for the purpose of heating the air is dispensed with, and that thereby one of the chief difficulties of the old caloric engine is avoided; for in the hot-air engine the fuel is contained in a fire-clay furnace surrounded by an air-tight iron casing, which in this way is entirely protected from injury. The fuel, which may be anthracite, smokeless coal, or coke, is thus burned under pressure with great regularity, and with the production of a uniform temperature, and at a rate exactly proportionate to the duty the engine is called upon to perform, thus avoiding all waste of fuel—a result which has not been attained with any form of engine yet introduced.

The heated air, together with the gases produced by the combustion of the fuel, pass from the fire-box directly into the cylinder, so that every unit of heat produced is converted into force. The piston consists of a hollow plunger, to which the piston-rod is attached; the packing is placed around its upper circumference, where the heat is so moderate as to permit of efficient packing and lubrication. By means of an air-pump worked by the piston, a supply of air is forced into the grate. It here comes in contact with the fire, and a portion of it, in maintaining combustion, combines with the carbon, producing carbonic acid, &c. ;while another portion of the air in excess takes up heat, and is thereby expanded. The mixed heated air and gaseous products of combustion speedily accumulate such an amount of expansive force as to set the engine in motion, by pressing on the piston. At the end of the stroke the expanded gases escape by the waste-pipe, which may be connected by a common stove-pipe with an ordinary chimney. Each upward stroke of the piston produces a downward corresponding stroke of the air-pump, and forces a fresh charge of cold air into the grate to maintain the combustion of the fuel, thus keeping up a continual supply of heated air and gaseous products. The power is increased or diminished by dampers, which pass the air through or over the fire, according to the amount required.

The chief advantages of the hot-air engine will be found in the very important facts, that there is not the most remote danger in its use. The furnace is perfectly insulated, so that all risk of fire is entirely avoided, and the presence of water, whether in large or small quantity, is dispensed with; so that this engine can be employed under circumstances where it would be impossible to use a steam-engine. Either of these engines will be found invaluable in the pharmaceutical laboratory or physical workshop. Each possesses advantages peculiar to itself, but both are free from the drawbacks attending the use of steam-engines, as they require no skilled labour, no water, do not increase insurance, make no dirt, and are entirely free from danger.

Meetings for the Week.

Tuesday, May 21.

Royal Institution, 3 p.m. Professor Miller "*On Spectrum Analysis.*"

Pathological Society, 8 p.m.

Wednesday, May 22.

Society of Arts, 8 p.m.

Geological Society, 8 p.m.

Thursday, May 23.

Royal Institution, 3 p.m. Professor Huxley "*On Ethnology.*"

Royal Society, 8½ p.m.

Friday, May 24.

Royal Institution, 8 p.m. Professor Herschel "*On the Falling Stars of 1866-67.*"

Quekett Microscopical Club, University College, 8 p.m. Mr. Ernest Hart "*On the Minute Structure of the Iris.*"

Saturday, May 25.

Royal Institution, 3 p.m. Professor Huxley "*On Ethnology.*"

NOTES AND QUERIES.

Calico Printing.—Sir,—Referring to your note upon calico printing in last week's publication, I shall have pleasure in arranging with "J. K. M" a permanent system of remuneration for the advantages he names, which, if reliable, will stimulate the aniline colour trade. If you will let me have the address of "J. K. M.," I will at once communicate with him.—R. E. B, Manchester.

Caramel Colours.—Sir,—I have noted the correspondence respecting caramel colours in the CHEMICAL NEWS, and I should be glad to learn where glucose can be obtained in manufacturing quantities. There was a "Glucose and Caramel Company" in existence some time since, but it is now defunct; and I am therefore at a loss where to obtain it, and cannot spare the time for making it.—J. W.

Map Varnish.—Sir,—I want to prepare a good map varnish which will dry rapidly If any of your correspondents will kindly instruct me in its preparation through the medium of your valuable section "Notes and Queries," they will confer a favour upon me.—J. S.

Artificial Teeth.—Sir,—Within the last few years some improvements have been made in the manufacture of artificial teeth, by which they are rendered less brittle. I am anxious to find directions for their preparation, and shall be happy to pay any person who will assist me in this matter.—F. T., Leeds.

Crystallisation of Chromates.—Sir,—During the crystallising of bichromate of potash, a coating of light lemon-coloured crystals formed on the front of the bichromate. These crystals did not, however, appear till the crystals of bichromate had almost done forming. The mother liquor at the time was about six or eight degrees warmer than the surrounding atmosphere. If the liquor was allowed to remain in the crystallising pans until perfectly cold, the crystals referred to would increase to four or six inches in thickness. The form of these crystals was an oblique four-sided prism. Now, this did not appear from want of sulphuric acid; if that was the case, the crystals would have been green. The amount of potash required to decompose the oxide of chromium was calculated correctly and added. Has any of your readers who may be acquainted with the manufacture of bichromate of potash ever noticed the formation of the crystals named, and to what cause can their appearance be traced? —H.

ANSWERS TO CORRESPONDENTS.

F. L. and M. P. S.—Your communications are declined, with thanks.

J. W. T. is informed that a letter from Canada, in reply to an advertisement, has been sent to our office.

M. Jenkins.—What is usually known as queen's metal is an alloy formed of two parts of tin and one part each of lead, antimony, and bismuth.

A Student.—The term "wad" is applied to two distinct minerals. It generally means an ore of manganese mixed with iron; but in Cumberland the term is applied to plumbago.

A. K.—Tetradymite consists of sulphide and tellurido of bismuth with impurities. Its name, however, is not derived from the fact of its being composed of four elements, but from its occurrence in quadruple crystals.

Clericus.—Chloroform is, perhaps, the best substance you can use for removing paint stains from oak. You must remember that it will likewise attack the varnish.

Communications have been received from S. Mellor; Dr. Adriani; F. Field; T. Sherlock; G. F. Rodwell; W. Webb; Price's Patent Candle Company; J. Sullivan; Lloyd Smith; the Walker Alkali Company; T. Parkins; C. Ogleby and Co.; J. Muspratt and Sons; J. F. MacFarlan and Co.; Davey, Yates, and Routledge; Allen and Hanbury; J. J. Vaughan; Professor B. Silliman (with enclosure); F. C. Calvert; Geological Society (with enclosure); Clericus; Henry Charlton; R. E. B.; J. V.; W. Gossage; Editors of Journal of Mining; William Schofield; E. Frankland (with enclosure); Runcorn Soap and Alkali Company (with enclosure); S. Muspratt, M.D., &c.; W. B.; A. C. Hadland and Co.; R. Wilkinson; Messrs. Denton and Co.; W. Bush; Pullar and Son.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On the Direct Estimation of Boracic Acid, by Professor F. Wöhler.

In order to estimate directly the boracic acid contained in datolite, $3(CaO,BO_3)+3CaO,3HO,4SiO_3$, place the mineral in a small tubulated retort, decompose it with hydrochloric acid, and distil the mixture to dryness; pour on to the residue the distillate (which contains boracic acid), and allow it to digest to separate the silica. In the liquid precipitate the lime by means of oxalate of potash, taking care not to add it in too great excess. Then, after filtration and concentration, precipitate the boracic acid in the form of double fluoride of boron and potassium. For this purpose, add a little potash to the material in a platinum capsule, then pour over the mixture a slight excess of hydrofluoric acid, and evaporate the solution to dryness. To remove the other salts it suffices to treat the mass with a moderately concentrated solution of acetate of potash; then allow it to digest and throw on to a filter the double fluoride of boron and potassium, and wash it with the same solution of acetate. Then wash with dilute alcohol to remove the acetate of potash; the double fluoride is then dried at 100° C. and weighed.

On Determining the Proportional Relation between Silver and Chloride of Ammonium, by Professor J. S. Stas.

The method of determination I used is that described in my former article. To prevent the loss of hydrochloric acid, which would have been set free by introducing chloride of ammonium into a hot acid solution of nitrate of silver, I neutralised with pure ammonia the excess of nitric acid used for dissolving the silver. The following is the manner in which I proceeded:—

After having added to the solution of silver in nitric acid 100 *cubic centimetres of water for each grain of metal* dissolved, I poured in, drop by drop, a solution of pure ammonia. When the liquid was alkaline, I neutralised it by a suitable addition of *pure acetic acid*.

In order that the double decomposition might take place under absolutely identical conditions, I neutralised with ammonia both the silver solution to be precipitated while cold, and that at 100°. In order that the solution should be about 100° at the moment of the double decomposition, I kept the flask or globe in which the assay was made in boiling water *for two hours*, and without removing it from the bath I introduced the chloride of ammonium. As the precipitation took place at a high temperature, the liquid cleared itself the moment a complete mixture of the reagents had taken place.

I weighed in air* the chloride of ammonium and the silver employed, assuming, according to Prout's hypothesis, the weight of the molecule of chloride of ammonium to be 53·50, and that of silver 108·00. The excess of the metal remaining in the liquid after the double decomposition was determined without removing the flask or globe from the bath. For this purpose I directed a pencil of yellow light to the surface of the liquid in which I wished to measure the silver. The comparative assay, made at the ordinary temperature, was performed by means of the apparatus for *titration*, described on page 137.

The following table contains the results of these three sets of experiments. I have added three determinations taken from my former work; they were made with chloride of ammonium produced at the ordinary temperature by combining directly solutions of ammonia and hydrochloric acid:—

Proportional Relation between Silver and Chloride of Ammonium.

Number of the experiment.	Weight of the sal ammoniac reduced for a vacuum.	Weight of the silver reduced for a vacuum.	Weight of the excess of silver after the double decomposition.	Chloride of ammonium which is equivalent to 100,000 parts of silver.
First Series.—Chloride produced at the Ordinary Temperature by combining Hydrochloric Acid with Solution of Ammonia, determined at the Ordinary Temperature.				
	gr.	gr.	gr.	
IX.†	11·0088	22·2236	0·0300	49·600
X.†	10·92896	22·06734	0·0280	49·599
XI.†	12·26038	24·74991	0·0305	49·598
Second Series.—Chloride sublimed at the Ordinary Pressure, Determination made at the Ordinary Temperature.				
	gr.	gr.	gr.	
I.	11·79643	23·8133	0·0290	49·598
III.	11·80844	23·8376	0·0290	49·597
V.	6·25216	12·62116	0·0140	49·593
VI.	10·71756	21·6355	0·0262	49·597
Third Series.—Chloride sublimed at the Ordinary Pressure, Determination made at 100° Centigrade.				
	gr.	gr.	gr.	
II.	39·62130	79·98313	0·0970	49·5974
IV.	13·40631	27·06320	0·0355	49·602
VII.	7·60107	15·3442	0·0187	49·597
Fourth Series.—Chloride Sublimed in a Vacuum, Determination made at the Ordinary Temperature.				
	gr.	gr.	gr.	
VIII.	13·5129	27·2784	0·0355	49·598
IX.	6·2250	12·5663	0·0140	49·592

The results given in the preceding table prove that, within the limit that must be allowed in making the experiments, *temperature exercises no influence upon the composition of chloride of ammonium or of chloride of silver; they prove further that pressure is without any influence upon the composition of chloride of ammonium.* In fact, whatever may be the mode of preparation of the compound of ammonium, and the temperature at which the double decomposition takes place, *its proportional relation to silver is constant.*

If the admitted constancy of the stable chemical combinations required to be demonstrated, it seems to me that the almost absolute identity of the results of the four series of determinations is sufficient to prove it. This constancy is the more remarkable, since sal ammoniac can, as I have observed, condense ammoniacal gas or hydrochloric acid, *in the same way that a number of bodies condense gases and vapours completely foreign to them in their constituent elements.*

Among the twelve determinations given in the table

* To reduce to a vacuum the chloride of ammonium weighed in air I weighed in the air and *in vacuo* a portion of the sal ammoniac that I intended to use. These assays convinced me of a fact that had already been stated by M. Marignac—viz., that the augmentation of weight obtained by weighing the pulverulent chloride directly *in vacuo* was always less than would have been calculated from the density. I found that 100,000 parts of pulverulent chloride weighed in air represented from 100,077 to 100,084 parts of the same compound weighed *in vacuo*. M. Marignac gives the figure 100,080 as the mean of the extremes. These weighings also showed me that the density of compact sal ammoniac differs appreciably, according as it is transparent and vitreous, or opaque and amorphous.

† These experiments are taken from my former work; the numbers of the experiments have been retained in the table.

there is one, No. II., which was made upon a quantity of material such as was never before employed in an experiment of this kind. I had a double object in using such large proportions. I wished to render sensible the influence of temperature upon the composition of chloride of silver, if there were any such influence; and then, as I was working with chloride of ammonium that had been sublimed three separate times, twice in vessels of *hard glass*, not attacked by the vapour of chlorine, it should be of an extraordinary purity, and I ought to be able to deduce an important consequence with reference to the hypothesis of Prout. Now, after the double decomposition had taken place upon the weights calculated according to Prout's hypothesis, there remained dissolved in the liquid 0·097 gr. of silver, being a quantity *one hundred times* greater than that which I could have appreciated in the mass of liquid, and certainly *fifty times* greater than that it is possible to measure by taking the trouble.

I invite those who think they can attribute "to errors of observation" or "to the impurity of the materials"‡ the differences observed between the experiment and Prout's hypothesis, to take the trouble of repeating, under the conditions necessary for exactitude, the determination of the proportional relation between chloride of ammonium and silver, and I shall wait with entire confidence the result of their investigation.

In speaking thus I do not pretend that the figures I have given are absolutely exact—that is to say, that they may not be affected by a constant error. I am even sure of the contrary, and in the conditions in which I was placed the constant error must have attained its maximum. In fact, the operation for deducing the proportional relation between the chloride and the silver involves an uncertainty to which I have already drawn the attention of chemists in my "*Recherches sur les Rapports Réciproques des Poids Atomiques.*" This uncertainty consists in the fact that an argentiferous liquid, from which nearly all the metal has been precipitated by a solution of chloride of potassium, sodium, or ammonium, but which still contains one or two milligrammes of silver per litre, precipitates both on the addition of a normal solution of silver and of an alkaline chloride. I find this phenomenon is the more pronounced the less acid the liquid is, and the more alkaline nitrate it contains. Now, in the double decompositions between nitrate of silver and chloride of ammonium, I was obliged, for the reason given above, to neutralise the excess of nitric acid by ammonia, and, for the same reason, I only added a slight excess of acetic acid. The conditions then, which are the primary cause of the uncertainty, are both present, and they must, as I have said before, bring the constant error to a maximum. But after allowing very largely for this constant error, there remains such a considerable difference between the calculated and observed results, that it is quite impossible to attribute it to any other cause than to the inexactitude of Prout's hypothesis.

Civil List Pensions.—The following pensions on the Civil List have been recently granted:—100*l.* a year to Lady Harris, widow of Sir William Snow Harris, in consideration of her husband's valuable invention of the system of lightning conductors. 100*l.* a year to the Rev. Miles Joseph Berkeley, on account of his eminent services, as a botanist, to practical horticulture and agriculture. 95*l.* a year to George Cruikshank, Esq., on account of his great merit as an artist.

PARIS EXHIBITION OF 1867.

(From our Special Correspondent.)

Gallery V.—Class 44: Chemical and Pharmaceutical Products.

We must not forget to mention, in a few words, the celebrated proprietor and director of the Pont-Labbé works, a real model establishment, M. L. Paisant. Founded in 1840 for the manufacture of starches and their conversion into alcohol, syrup, and dextrine, it was very soon affected by the potato disease. The establishment is not now confined to its original manufactures; it produces all sorts of chemical substances from the seaweed so abounding on the Brittany coast. It consumes at present 1800 tons of raw material, and delivers to commerce in places far inland 160,000 litres of kelp or lixiviating ash produced from seaweed. It is extensively used as an excellent manure over a great portion of Finisterre.

M. Paisant is a great manufacturer, much esteemed by all the inhabitants, and the jury should take him into consideration. He has developed his establishment on a large scale; he has paid great attention to the welfare of the population among which he dwells, and has ameliorated the condition of the working classes physically and morally, increasing their wages, constructing their dwellings, which leave nothing to be desired as to salubrity, and has founded a mutual helping savings bank, in case of the stopping of work or sickness, and for the relief of women and children.

In the first rank of the manufacturers of chemical products we must place M. Deiss, of Paris, Marseilles, and Lyons, the originator of the fabrication of sulphuret of carbon, and its use in the extraction of all fatty matters. In 1847, sulphuret of carbon, produced in a laboratory, cost 60 francs the kilogramme. In 1867, M. Deiss sells it at the rate of 35 centimes (3½d.) a kilogramme. In 1848 the treatment of caoutchouc by sulphuret of carbon was hardly known. Sulphuret of carbon now takes up, from the residues of many industries, several millions of kilogrammes of fatty matters hitherto thrown away; and this application is one of the most brilliant discoveries of modern times. No matter how powerful the presses, a considerable quantity of oil is left in the cakes of oleaginous seeds. The sulphuret of carbon supplies, wonderfully, a remedy for this imperfection, by taking out all the remaining oil. Paris, Brussels, Lyons, and Marseilles possess large establishments for the extraction of the hitherto lost fatty matters. Since 1862, these industrial works have been well appreciated by the juries. Dr. Hofmann placed them in the first rank. Since a few years back, they have attained an enormous size. At the Carthusian Friary of Marseilles, Boulevard Achard, a gigantic extractor treats, in 36 hours, 43 cubic metres of pulp or lees of olive, using 45 tons of sulphuret of carbon, which penetrates into the whole mass, takes up the oil, and deposits it in the distilling apparatus. The sulphuret of carbon is then passed through a worm, regenerated, and condensed, without any sensible loss, ready to take up another quantity of oil. Thirty to thirty-five tons of oily substances are thus extracted at each operation.

At Lyons they used to throw into the Rhone, annually, the oil that might have been used for making 5000 tons of soap. Now, on the contrary, the application is complete: oil in its neutral state is entirely utilised, and the process of M. Deiss is welcomed in the industrial arts.

M. Collas, our esteemed friend and neighbour, No. 8, Rue Dauphine, was the first to introduce in France, about 1840, the manufacture, mechanically, of medical lozenges. They are stamped out as in the Mint, like coins of different shapes, and bear inscriptions indicative of quality and the method of using them. He discovered, in 1848, benzine in coal oil, and at once introduced it into

commerce for cleansing stuffs; also nitro-benzine, which is a cheap substitute for the essence of bitter almonds. The creation of this substance really led to the beautiful aniline colours. The Society of Mulhouse said of him, in their meeting of March 22—"M. Collas has introduced into commerce benzine and nitro-benzine; the first seems for taking out stains from stuffs, the second is used in perfumery; . . . . . he has not found out any colouring matter, but we are now in possession of a product hitherto impossible to be procured. Dr. Hofmann repeated the experiments of M. Runge on kyanol (aniline). . . . . Perkin reproduced a reaction first indicated by Berzelius, and a great industry has been created. . . . . ." Thus the Mulhouse Society give all the credit to M. Collas for the means of making aniline colours.

Phosphates of lime, considered in the light of physiology and pharmacy, have been one of the favourite studies of M. Collas. He discovered and demonstrated by experiment that gelatinous phosphate of lime possessed the singular property of facilitating the putrefaction of animal matters. It acts under these circumstances not as forming, but as aiding powerfully, the development of those infusoria which determine the decomposition of animal matters. Thus it is a powerful digestive agent, and as experiments prove that diabetes and glucolucie depend upon the nature of the blood, and that the excellent preparations of phosphate of soda of M. Collas, his phosphoric lemonade, and milk of hydrated phosphate of lime are most successful.

During these last years, stimulated by the experiments of M. Lucie, M. Collas prepares iron reduced by electricity, quite pure, by aid of one Bunsen pile acting on chloride of iron in solution. The iron is deposited as a coating, while the several impurities fall to the bottom, leaving the iron quite pure. Obtained thus in grains or in very friable plates, it is easily reduced to an impalpable powder, like the copper of M. Oudry. It is, however, very oxidisable, and is obliged to be enclosed, for medical use, in gelatine capsules. Each capsule full of iron weighs 10 grammes and 50 centigrammes (or about 162 grains); the maximum dose per diem is five capsules, and observations continually prove the striking efficacy of the administration of metallic iron.

We recollect having seen in the glass case of M. Rousseau, another first-class maker of chemical products, a great phial of iron reduced by electricity, which was very astonishing to behold. It was not black like that of M. Collas, but it had the grey metallic colour of iron. He founded in 1843 an establishment for the fabrication and sale of chemical products and apparatus necessary for physical manipulation and the instruction of students. For twenty years he resided in the Rue de l'Ecole de Médecine, and three years ago he removed to the Rue des Ecoles. His customers have increased daily under our very eyes, and this augmentation proves that he has well fulfilled his engagements towards the public. In Class 44, M. Rousseau shows what he ordinarily manufactures and delivers for sale:—1. Specimens or samples of products and reagents. 2. A series of oxides and salts for colouring silicates, the cost of which he has lowered without diminishing the quality, so as to compete favourably with foreign markets. 3. Masses of sodium that he was the first to manufacture commercially and cheaply, so as to render aluminium available at a moderate cost, and on which account M. Sainte-Claire Deville made him one of his partners. 4. Magnesium also prepared for sale commercially, along with other metals recently discovered—such as cæsium, rubidium, thallium, &c. 5. Pyrogallic acid for photographic purposes, of which he sells 1500 to 1800 kilos. per annum. 6. Benzoic acid employed in the preparation of aniline colours; of this he undoubtedly extracts several thousands of tons every year from the urine of cows, carefully collected from the numerous dairies about Paris. Before he began his work all the benzoic acid consumed in France came from Germany. The great aim of M. Rousseau is to give to the commercial world, at a reasonable price, materials which were unattainable with profit by the manufacturing world. He exhibits in Class 51 a stove, which advantageously replaces that of Gay-Lussac, and which only costs 25 fr. instead of 45 fr.; a new densimeter easily employed; plates and cylinders of artificial carbon for the cheap use of Bunsen's batteries. He also shows in Class 90, marked at the price of 200 fr. (8l.), a collection of products for the elementary instruction of chemical students, with an explanatory volume. We mention other innovations made in France by the same distinguished hand. In 1839 he patented the first process for obtaining sulphuric acid from pyrites; there was at that time a great establishment at Javel, but sulphur, then at a high price, suddenly fell in the market, and pyrites could no longer compete with it. To M. Rousseau is due, also, the first idea of the agglomerated coal, or "Charbons de Paris," extensively used in France for culinary purposes. M. Popelin-du-Cazze, who bought the patent, has been very successful on the large scale. In 1849 he organised the mode of extraction of sugar by the double action of lime and carbonic acid, which has now been followed for the last twenty-four years under the name of Rousseau's process by all Europe. He also discovered a decolorising charcoal black at a cheap price—6 fr. the 100 kilogs. (220·5 lbs.)—for refining, in place of the cumbersome and dirty substances formerly used.

M. Huillard, the elder, of Paris, exhibits as the special objects manufactured by him orseille, orcine, orceine, eriphthine, eryphic acid, &c. The other mineral substances, the protoxide and sesquioxide of cobalt, and five carbonates, the arseniate, phosphate, silicate, borate, sulphate, nitrate, and chloride of cobalt; and the carbonate, nitrate, and chloride of cadmium are admirably crystallised. These are very creditable, and reflect much honour upon M. Jourdin, the young and energetic superintendent of the works, who is actively engaged in solving the following problems:—1. The delivery to commerce of orseille, liquid orseille, orcelline, extract of orseille, or imperial red. 2. The production on a large scale of cobalt blues to rival those of Germany. M. Huillard has succeeded in rendering lower the price of cobalt blues for stuffs and wall-paper, while at the same time they are more durably fixed. The Bank of France has adopted them for the 100 fr. bank-notes, inimitable by any photographic process; also for the 20 centimes (blue twopenny) postage stamps, though they are of a greenish hue by candle-light, but readily distinguishable from the others.

M. Eusèbe, of Paris, exhibits some very fine aniline greens and reds obtained by carbo-humic acid. He has yielded the full right of manufacture to M. J. J. Müller, of Basle. He has two magnificent collections of samples which can rival with any of the other manufacturers in the Palace.

M. Jean Rod has already received our compliments for the splendid specimen of crystallised and almost white rosaniline. He challenges the first markets of Paris or London and the greatest houses to produce better. He produces daily 175 kilos. of muriate of rosaniline, aniline blues, violet, and greens. He also produces, with the same substances, and delivers to the commercial world—hydrochlorate of aniline, a red dye; hydrate of monophenylic rosaniline, giving a reddish-violet tint; hydrochlorate of diphenylic rosaniline, giving a blue violet; hydrochlorate of triphenylic rosaniline, giving a blue dye.

In another collection of violets exhibited by him under the name of Parma or Alexandria violet, in the preparation of which ethyl replaces phenyl—Hofmann's process—exhibited also by M. Menier, M. Rod exhibits a cup of 500 grammes (1⅛ lb. avoirdupois) of cyanide or quinoline blue. To enumerate the splendid display of M. Rod would be too much for our space; suffice it to say that we warmly recommend him to the attention of the jury.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, May 16.

F. A. Abel, Esq., F.R.S., *Vice-President, in the Chair.*

The minutes of the previous meeting were read and confirmed; Mr. F. W. Peterson was formally admitted a Fellow of the Society; and the names of William Phipson Beale, barrister-at-law, Stone Buildings; Alfred Coleman, Plough Court, Lombard Street; and Augustus Alfred Wood, 74, Cheapside, were read for the second time.

Mr. Perkin, F.R.S., said he had a few observations to make upon some experiments with which he had been lately engaged. Coumarine, it is well known, is the crystalline principle of the Tonka bean, and was first analysed by Delalande and afterwards by Bleibtren. The formula of this substance is $C_9H_6O_2$. When heated with potash, it assimilates an equivalent of water, and becomes converted into coumaric acid $C_9H_8O_3$. This, again, if fused with potash, yields salicylic and acetic acids, with evolution of hydrogen. On account of this latter transformation, coumarine is viewed as a derivative of salicyle. Having been lately a good deal engaged with the study of salicyle derivatives, he had often endeavoured to obtain some clue to the constitution of coumarine, hoping that he might eventually be able to build it up from some salicyle compound. About ten days or a fortnight ago he obtained a beautiful crystalline product, possessing both the odour and composition of coumarine. When heated with potash, it yielded an acid, apparently identical with coumaric acid, and on fusing it with potash it was converted into salicylic acid—it was, in fact, artificial coumarine. He had not compared it side by side with the natural product, but expected to do so in the course of a few days. As he hoped shortly to bring an account of his results before the Society, he would refrain from entering into further details, except to state that he obtained his product from the sodium derivative of salicyle by means of acetic anhydride. Knowing the interest that chemists generally take in the artificial formation of natural products, he thought these remarks would not be unacceptable.

An elaborate paper "*On the Constitution of the Phosphites*," by Professor C. Rammelsberg, was read by the Secretary. The author commences with an historical notice of previous researches, which appear to have left unsolved the amount of water, or rather the condition of the hydrogen, contained in the salts of phosphorous acid, so that the constitution of these bodies might be represented by one or other of the following formulæ:—

$$H_2R''_2P_2O_6 \text{ and } H_4R''_2P_2O_7.$$

To elucidate this question, the author prepared and analysed a great many different phosphites, and the results in the case of the dyadic metals warrant the adoption of the second formula. Thus the barium and nickel salts have precisely the above composition, the strontium and calcium salts containing extra two atoms of water, and magnesium salts were prepared containing respectively five and twelve atoms of water of crystallisation. Zinc and magnesium appear, however, to give rise to the production of salts of two classes, whilst lead, copper, manganese, &c., always form compounds containing one atom of hydrogen which cannot be replaced by a metal.

Class A.	Class B.
HK_2PO_3	$H_4Ba_2P_2O_7$
$HMnPO_3$	$H_4Ca_2P_2O_7$
$HZnPO_3$	$H_4Mg_2P_2O_7$
$HPbPO_3$	$[H_4Zn_2P_2O_7]$
$[HMgPO_3]$	

Phosphorous acid seems to be incapable of forming acid salts. The crystallised acid itself contains one atom of water, and any attempt to expel the latter by the application of heat destroys the substance, with evolution of gaseous phosphide of hydrogen.*

After the Chairman had moved a vote of thanks to the author, and invited discussion upon the subject of the communication,

Dr. J. H. Gladstone said it was sometimes easy to build up a compound and speculate upon its constitution, if we knew already the nature of the body from which it was prepared. The starting-point in this case was the terchloride of phosphorus, which, undergoing decomposition by water, furnished the acid in question:—

$$PCl_3 + 3H_2O = 3HCl + H_3PO_3.$$

The acid itself was stated, by Prof. Rammelsberg, to have the following composition:—$H_4P_2O_5 + H_2O$. To obtain this result, there were two stages, the first or intermediate product being the oxychloride of phosphorus—

$$\text{I. } 2(PCl_3) + \left.\begin{matrix}H\\H\end{matrix}\right\}O = \left.\begin{matrix}PCl_2\\PCl_2\end{matrix}\right\}O + 2HCl.$$

$$\text{II. } \left.\begin{matrix}PCl_2\\PCl_2\end{matrix}\right\}O + 4H_2O = \left.\begin{matrix}P(HO)_2\\P(HO)_2\end{matrix}\right\}O + 4HCl.$$

The Secretary then read a paper by Dr. A. Dupré "*On the Changes in the Proportion of Acid and Sugar present in Grapes during the Progress of Ripening.*" It has frequently been inferred that the tartaric and malic acids in grape-juice become transformed into sugar during the process of ripening; but the author's experiments tend to disprove this assertion. Dr. Dupré collected and experimented upon a hundred berries of Riesling grapes gathered at intervals of a month, commencing with September last, and the amounts of tartaric acid, free and combined, and also of sugar, were determined in the separated juices. The proportion of sugar increased in order of time from 2·98 to 12·10, and even to 16·20 per cent. in the juice of the perfectly ripe fruit; whilst the entire berries showed but a slight diminution or no appreciable change in the total amount of acid present. The saccharine matter could not, therefore, have been directly derived from the organic acid or its salts contained in the grape; but the author thinks it possible that the presence of such acid effects a change resulting in the production of sugar similar to that known to occur in the conversion of starch into sugar by the action of sulphuric and other acids. Further experiments, even more decisive in their character, were made upon Gutedel and Muscatel grapes, gathered at the same time and from the same vine, but in various stages of ripeness. In some of the unripe berries there was absolutely no sugar, whilst in others nearly ripe 8·87 per cent. of sugar was found; but the amount of free acid estimated in a hundred grapes was almost the same in three samples of Gutedel, and actually increased with the ripening of the Muscatel.

Another paper, by the same author, was then read. It is entitled, "*On some of the Effects produced by the Addition of Plaster of Paris to Must.*" It seems to be a common practice in the wine-growing countries to add the substance named in the heading to grape-juice either before or during the process of fermentation, the alleged object being to increase the richness of the must by the absorption of water. Although this action doubtless occurs, the author points out that the loss of material in the course of such treatment (by mechanical retention in the gypsum) never compensates for the augmentation of sugar in the remaining juice, and suggests that a partial evaporation should be resorted to, or some sugar added instead of the earthy sulphate. Numerical results are quoted in support of this assertion, and the chemical changes induced by the employment of the plaster are fully stated. Consisting, as it does, of sulphate with a little carbonate of lime, it not only decomposes the tartrates in the grape, with liberation of the purgative sulphate of potash, but also neutralises and removes some

* An earlier statement respecting the phosphites, by the same author, appeared at page 241 of the present volume.—Ed. *C. N.*

of the free tartaric acid—an essential constituent of wine—leaving the malic acid still soluble, thus deteriorating, says the author, the condition of the juice, and assimilating it to the quality of that obtained from unripe fruit. Wine made according to the above system will be characterised—1st, by a more or less complete absence of tartaric acid; 2nd, by containing sulphates in solution; and 3rd, by giving, on incineration of the residue, a larger proportion of ash and diminished amounts both of phosphate and carbonate.

Dr. Odling, in answer to Colonel Yorke, said that chloride of barium always indicated the presence of dissolved sulphates in sherry, but gave no precipitate in a true claret.

The Secretary then proceeded to describe "*An Adapter to be used in connexion with Sulphuretted Hydrogen Apparatus*," by the Rev. B. W. Gibsone, M.A., B.Sc. This arrangement consists of an ordinary glass funnel, the limb of which fits into a conical bung of vulcanised india-rubber, whilst the top is covered with a flat plate of the same material, perforated with three holes, through one of which a current of sulphuretted hydrogen is made to enter, another aperture serving as the exit pipe for the excess of gas, which it is proposed to absorb by passing through a succession of Woulff's bottles charged with ammonia. The third is a spare hole usually closed with a stopper. Within the funnel itself is a long glass tube, with a thistle-shaped expansion at top, into which is fitted a cork and short piece of tube for connexion with the central aperture above it, and this funnel tube has also within it a cane of glass rod of greater length than itself, with a bead placed inside the thistle as a means of lifting it from close contact with the apex of the larger funnel, which is kept moistened with water. When thus lifted a current of the gas makes its escape from the lower orifice of the funnel, and is made available by passing through any solution contained in the bottle to which the bung and adapter are fitted. When the action is completed the flow of gas is stopped simply by removing the vessel, when the weight of the glass rod causes the funnel tube to descend, and no more gas can pass. For a description of his sulphuretted hydrogen generator the author referred to a sketch of the apparatus which had already appeared in the Chemical News (*vide* p. 240 of present volume).

An elaborate paper "*On the Practical Loss of Soda in the Alkali Manufacture*," was then read by Mr. C. R. Wright, B.Sc. The author has had an opportunity of studying the minute details of Le Blanc's process as carried out in a large factory making upwards of 150 tons of alkali weekly, and the products were examined at every stage for the purpose of ascertaining the loss of soda during the process of conversion. A capital series of analyses are given, which show the average composition of salt cake, black ash, soda ash, refined ash, and the dried vat waste, which last seems to contain a notable quantity of alkali, both in the soluble and insoluble states. The total loss of sodium in the process of converting salt into refined soda ash is set down at 20·24 per cent., and consists of the following items:—

	Per cent.
Previous to Lixiviation.	
Sulphate of sodium left undecomposed	3·49
Insoluble sodic compounds formed	5·44
Volatilisation of sodic compounds	1·14
During and after Lixiviation.	
Soluble alkali left in vat waste	3·61
Oxidation of sulphide of sodium	—
Leakage and losses in white ash process	6·56
Total loss	20·24

The speaker made reference to the previous researches of Mr. Kynaston,† and also to those of Mr. James Hargreaves lately published in the Chemical News. The last-named gentleman affirms that one-seventh part of the chloride of sodium escapes conversion into sodic carbonate, or is lost in the process of manufacture.

The Chairman moved a vote of thanks to the authors of the respective communications, and, at a late hour, adjourned the meeting until June 6, when Sir Benjamin Brodie will deliver a lecture "*On Ideal Chemistry*."

ROYAL INSTITUTION.

Tuesday, May 14, 1867.

A Course of Four Lectures on Spectrum Analysis with its Applications to Astronomy, by* William Allen Miller, *M.D., LL.D., Treasurer and V.P.R.S., Professor of Chemistry, King's College, London.*

Lecture I.

Nature of the Prismatic Spectrum.—Spectra of Solids.—Spectra of Gases and Vapours.—Spectra produced by Absorption.—Spectra of Rays of Heat, of Light, and of Chemical Action.

My object in the course of lectures upon which we enter to-day will be to endeavour to place before you distinctly the mode in which, by the optical analysis of light from various sources, we have learned not only to distinguish the physical condition of the body which emits that light, but also, in many cases, to ascertain its composition.

A new method of investigation is thus placed in our hands. The mode of analysis, it is true, has been practised before to a certain extent, but it involves the application of principles which, until quite recently, had been overlooked. It enables us to deal with matter at infinite distances, for, provided we can see it, we are able to examine it by this optical method. It also enables us to examine matter in quantities so minute that no balance can estimate its amount. We are therefore brought face to face, by its means, with infinitude of space and distance, and infinitude of minuteness.

I know that those who have been in the habit of attending lectures at this Institution have from time to time watched with interest the progress of this new branch of investigation. They have had opportunities from time to time of seeing the steps, by which it has been raised to its present position, illustrated and experimented on; but although many who may be honouring me with their attendance on this occasion may not for the first time be considering these wonderful phenomena, the intrinsic interest which they possess—the variety and beauty of experimental illustration of which they admit—induce me to hope that even those who are in some measure familiar with the facts will yet be able to follow me with interest through the theoretical considerations which I may have to bring before them, and through the somewhat minute detail upon which, from time to time, I shall have to enter.

Without further preface, then, let me proceed to the examination of the method of inquiry—the method of optical analysis.

No doubt every one present knows what is meant by the prismatic spectrum. If we take a beam of white light, and transmit it through a triangular mass of glass properly cut and polished, we divert it from its original direction—we refract it from its course. Now, light may be artificially produced in various ways, and one of the most general of these modes of obtaining light consists in raising the temperature of the body which is to be experimented upon. Every opaque solid object gives out light in large quantity when its temperature is sufficiently raised. At a temperature of about a thousand degrees of Fahrenheit every substance becomes what is called red-hot—that is to say, begins to emit red light. As we raise the temperature, the colour of the light

* Reported specially for this paper, and revised by the author.

becomes more brilliant, and it passes at length into a dazzling white. That is a general effect whenever any solid opaque substance is sufficiently heated. I shall take advantage of this fact in order to be able to produce the beam of light upon which we shall have to experiment in a part of this investigation, and for this purpose it will be my desire to show you, first of all, the solid body itself which is producing the light, because, hereafter, I shall have to show you other sources of light which are not solid, and which are giving out light of a different kind.

In the first place, then, I shall, by the powerful heat produced by the current of electricity of the voltaic battery, cause intense ignition of two points of charcoal. You will excuse me if from time to time in these lectures I bring before you what appear to be very simple experiments. Philosophically, nothing is trifling if it proves a principle. In this case I shall throw upon the screen the image of the two charcoal points. My object here is simply that you may see that although we get an intense light and a white light, it is produced by a body in the solid state. The charcoal points do not melt, and there is no visible vapour given off. I do not say there is no vapour given off, but there is none visible. On throwing this image upon the screen, we shall see, first of all, the incandescent points themselves, separated from each other to a considerable distance. Having shown you the points, we will then examine optically the nature of the light which those points are emitting.

You will observe that the image of the line of light is produced by allowing simply a thin slice of light to pass through a very narrow slit. It is now falling upon the surface of a mirror, and from that mirror it is reflected upon the screen. We will now withdraw the mirror altogether, and allow the light to pass through the prisms which have been arranged for its dispersion. So long as these points of ignited matter are in the solid condition, we have that beautiful elongated image which now appears upon the screen, and which is, in fact, composed of a series of slices of light, each of which is of a particular and definite colour. You will notice that the extremity which is nearest to me—the red—is that which is least refracted from the original direction, and the extremity which is farthest from me—the violet—is that which is most refracted from the original direction. Now, the point I particularly wish to insist upon in this observation is that we are here dealing with a *solid* body, which is not capable of being converted into vapour so as to produce flame. If time allowed, I should like to show that this, which is observed in the case of charcoal, is a general fact with regard to solid bodies. For example, if, instead of heating charcoal points by the voltaic current, I were to take a cylinder of lime and introduce it into the intense heat of the oxy-hydrogen jet, or if I were to take a piece of magnesium, a piece of silica, a mass of iron, or a mass of platinum, and heat it so as to produce incandescence or intense ignition, the spectrum which would be obtained from its light would, in every case, when examined, be seen to be continuous, like that charcoal spectrum. [I dare say you noticed flashes of light which crossed that spectrum from time to time. They were due to slight impurities in the charcoal points, and these impurities become volatilised in the intense heat. With them we shall have presently to deal.] The particular fact upon which I wish now to insist is that, as a general rule, whenever a solid body is heated, it gives out light, which, when examined by the prism, furnishes us with a continuous spectrum. That is to say, this light is made up of an infinite number of slices of light. By means of a rough model, I may make this more clear. Suppose that this white bar represents to us a band of white light—the light, in fact, which we first got before it is dispersed by the prism. If we cause it to pass through the prism, it is spread out in this fan-like manner, every piece of that spectrum being composed of a slice of light of the particular colour which is there represented; and these slices of light, overlapping each other continuously, produce that blending of colour which is inimitable by art, but which is so brilliant and so beautiful in its effect.

These, then, are the results of the examination of bodies in the solid condition, and for the purpose of recalling this to your mind we have here a diagram representing the spectrum of any sufficiently luminous solid body. And, further, if the solid happens to melt, it still gives out a continuous spectrum. A mass of melted cast-iron, for instance, would furnish a continuous spectrum, as in the case of charcoal. Or if we were to take any other metal which can be heated sufficiently to be melted without boiling and volatilising, we should obtain a similar result. I cannot show you this experiment, because I am not able by means of the voltaic battery sufficiently to regulate the heat.

Here let me notice that in spectra of this kind we have no clue to the chemical nature of the body which produces the spectrum. But if we go a step further, and heat the body sufficiently to convert it into vapour, the spectrum which is then obtained is quite of a different nature. Instead of having a continuous spectrum, we shall have an interrupted spectrum; and I am going now to prove to you that the body upon which I am experimenting is converted into vapour before it furnishes a spectrum, and for this purpose shall introduce into the lamp a charcoal cup, upon which we shall place a piece of silver. That silver will immediately melt with the intense heat of the current, and as the current is continued, it will not merely melt, but it will actually boil, and become distilled. In fact, silver has been distilled on a large scale by Stas, for the purpose of its purification. [The image of the charcoal points on which the silver was placed, was thrown on the screen.] That beautiful green arc is the vapour of silver. The silver, you will remember, appears on the upper part of the screen, in consequence of the inversion of the image. What in the lamp is the lower part is here upon the screen the upper part. You will see a number of little glowing points, which are the distilled silver. Well, now, if we could manage to open out these glowing points of melted silver (but which we cannot in the present form of our experiment), we should see that they were giving out light of all colours, but the arc itself is giving out light of a particular colour.

We shall now examine the mode of discriminating between silver and other bodies, by means of this process of optical analysis. In another lamp I have exactly the same arrangement as that which you have here seen thrown upon the screen; but, instead of making the image of the points fall directly upon the screen, I shall let a slice of light only fall upon a lens in front of the slit, and then upon a prism. Now, you will notice that the instant the temperature rises sufficiently we get these two magnificent green bands. These two bands are the characteristic marks of silver in vapour. They constitute the arc of light which we saw just now upon the screen, and which is here, by means of the prism, spread into its component parts. You will notice that there is on the ground of these bands a small amount of light, which is due to the dispersion of the light from the charcoal points. We cannot avoid that. In these cases we do not get the pure light of the substance upon the points, because the heat which is produced is sufficient to give us a tolerably strong spectrum of the charcoal points. But you will observe how very much those green lines predominate over the other light in that spectrum.

The next fact which I have to bring before you is that, though every substance which is capable of being converted into vapour gives a spectrum, it gives a spectrum *of its own*. If you take substances which to the naked eye appear to possess exactly the same colour, the moment you place them in the voltaic arc the vapour given out by each is capable of being distinguished from the others',

and you have a different spectrum for each body. I will illustrate this by means of four different bodies, each giving a green light. I have shown you the spectrum of silver. Now I will take three other bodies, each giving a green light differing a little in its shade from that of the others. The first of these will be metallic copper, which, like other metals, will boil in the intense heat we can here produce. The vapour of copper will give us a spectrum of its own, which, although green, will not be the same as the spectrum of silver. [The spectrum was shown on the screen.] There you see a series of green bands, but in the case of copper there is also a large quantity of red and orange light. You see a series of channeled or grooved spaces through a pale background, due to the light from the charcoal points themselves; but the brilliant portion of the spectrum is produced by the volatilisation of the metal. You will be able readily to contrast this copper spectrum with the spectrum of the silver which we had before. Here, you observe, we have a green, but a green of a different order. Copper is a more fixed metal than silver, but by means of this intense heat it becomes converted into vapour. Solid copper, if heated, would not give us this line, but a continuous spectrum like lime and like charcoal.

I am now going to take another metal, which also gives us a green light, and I have a special reason for selecting this metal—magnesium—because we shall consider it from another point of view hereafter. Magnesium is a metal which, when burned with proper precautions, gives rise to a beautiful green light. I dare say we shall see some blue also, but the principal part of the magnesium spectrum will be a green light, but a green of a different shade from the others. In this case you will not see the fact that the green light of magnesium is concentrated into three bands. These three bands are so exceedingly close together that the apparatus we have at our disposal for throwing them on the screen does not enable us to separate them. In this spectrum of magnesium you will see a certain blue line, and there is also a faint line nearer to the yellow.

The fourth metal which I have selected also gives a green light, and this is likewise an extremely interesting body. It is thallium, a metal which was discovered by the application of the method of spectrum analysis. [The spectrum was produced.] That is the band which is perfectly characteristic of thallium. Whenever we have pure thallium we have that single intense green line.

From these experiments it is obvious at any rate that these four substances have totally distinct spectra, although the light which these metals emit appears similar when viewed without the prism. If we were to throw slices of their light directly upon the screen, we should not be able to distinguish these metals from one another; yet, by spreading them out in this fan-like form by prismatic analysis, it is easy to distinguish one from the other.

We have then here a second set of spectra, and these spectra are such as are represented in the second of our diagrams. They are spectra which are not continuous—interrupted spectra—spectra with bright lines. These occur in the case of flames and ignited vapours and gases. It is true that in one instance a solid body has been known to give out lines like this, but it is a substance which I suppose not a dozen people have ever seen. Still it is an important fact that the metal erbium, in the form of its oxide erbia, even in the solid, has the power of giving out bright lines when its spectrum is viewed. This is an awkward fact for the theory of spectrum analysis, but at the same time it is one which must not be ignored. We are always discovering facts which do not square with our theories; and the more these facts are examined, the more surely are we led on to correct our theories, formed, as they always necessarily are, from partial knowledge only. This exception in the case of erbium does not, however, invalidate the general conclusion that whenever we see a body which emits a spectrum having bright lines, that body is in a gaseous condition. We do not as yet know why erbium makes an exception, though at some future time, probably, we shall be able to account for the apparent anomaly, the discovery of which we owe to the observations of Bunsen, to whom also we are indebted for a great part of our knowledge of spectral phenomena.

We must now turn our attention to the cause of these remarkable phenomena; and here I must ask you to follow me for a few moments through a little speculation—not that it is new, but it is speculation which is necessary to connect our ideas—speculation as to what light is. The notion of the nature of light which is at present adopted by philosophers is of this kind:—Filling all space, and filling the interstices of all kinds of matter, there is a subtle something which, for want of a better name, is called "ether." This ether has no weight. It is not light itself, although it is the means by which light is manifested to us. (Mind, this is all speculation, but still it is necessary.) When this ether is thrown into vibration, the vibrations are transmitted through space in right lines, radiating in all directions from the point at which the vibration is produced. When these vibrations have a certain degree of frequency, they produce the phenomena of radiant heat; when they have a somewhat greater frequency, they produce phenomena which are manifested to us in the shape of light; and when these vibrations are more frequent still, they produce phenomena which are manifested to us in chemical effects, or in those effects which Professor Stokes has taught us to associate with the term "fluorescence." Now, the different degrees of frequency with which the ether can be made to vibrate give rise to certain phenomena in light. Not merely is light a vibration of one particular frequency, but the different kinds of light are produced by vibrations differing in the degree of their frequency. Those portions of light which are least refracted (the red) are produced by vibrations of the ether of the lowest frequency; those portions which are most refracted (the violet) are produced by vibrations which are of the greatest frequency; and intermediate between these we have vibrations which produce all the intermediate colours. Now, although it is true every one here is prepared to hear wonderful statements of this kind, I was going to say I scarcely dare to mention the number of these vibrations which it is calculated must occur. Let me first tell you what the width of a wave of light must be. Every wave of this ether, as I have stated, is liable to vary in width according to the colour of the light. In red light the width of a wave is about the 34,000th part of an inch. A wave of violet light is a little more than the 60,000th of an inch—that is to say, there would be a series of 60,000 of these little waves in the space of an inch. That seems a tolerable number, but when we come to the frequency with which these undulations succeed each other, it is perfectly marvellous. In red light there are 482 millions of millions in a second of time, and there are upwards of 707 millions of millions in the case of violet; and we may fill up the interval of the intermediate colours with every conceivable variety between the two.

Now, it is very difficult, when one is looking at these things for the first time—and, indeed, it is always difficult—really to grasp these things, and therefore it is needful that we should come down to something a little more within our ordinary range of conception. I shall, therefore, take an illustration or two from another set of vibrations which you had most admirably illustrated not long since by Professor Tyndall. I cannot help reminding you of one or two beautiful experiments which he brought before you, and which show the beautiful analogy between colour and sound, for, in point of fact, red is the bass of light and violet the treble. You all know that musical notes are produced by a certain series

of vibrations which occur in definite number and at perfectly regular intervals, each note having its own specific number of vibrations—the middle C, for instance, in a pianoforte having 256 vibrations in a second. C in the octave above has double that number, or 512. Here is a tuning-fork which will give us a note which will cause the air in this box to vibrate. [The fork was struck, and held over the mouth of the box, whereon a musical note was obtained.] This fork is producing a certain number of vibrations, which vibrations correspond to a column of air of a particular length contained in the box. Now, if I take another of these forks and hold it over the next box, we get a note which is the octave above. [Experiment performed.] There are twice the number of vibrations in that sound as there were in the sound which I produced first. In the case of musical notes we have a series of these sounds succeeding each other in order. Now we take another fork, and hold it over the next box; then again, the next; and then the last, this being the highest of all. [A musical sound was evoked in each case, each successive note being higher than the preceding.] Now, these are, in point of fact, to sound, what colours are to light. In the case of light, we cannot get through the octave. If we assume that the proportion of vibrations in red light be 100, those for the violet light will not exceed 175; so that the number of vibrations, immense as it is in the case of light, does not embrace so wide a range as in the case of sound, for we may have musical vibrations ranging from 16 in a second to upwards of 2000 in a second.

I have no doubt that many of you know the beautiful experiment which I first saw performed by Dr. Tyndall here, and it is so beautiful that I cannot help desiring to show it to you again, although I may not succeed so well as he does, because it is a matter which he has made his own. The experiment is this:—If we take two tuning-forks, one of them an octave above the other, and each having a thin wire attached to the limb of the fork, and cause them to vibrate, and if we then draw them at the same rate across a piece of smoked glass, we shall have a sinuous line, which will represent the motions of each fork. [A piece of smoked glass was marked as described.] We will put this into the lantern, and you will see on the screen two sinuous lines, one above the other. The lower line is that which is produced by the bass sound; the upper one is that which is produced by the higher sound. The sinuosities in the upper line are double the number of those in the line below. In this we have ocular proof of the difference between the rate of vibration of the two forks. If we were to rule lines across, we should find that the bends in one of these lines were twice as numerous as in the other. This is one of the simplest and, at the same time, the readiest proofs we can have of the difference in the vibrations.

Now I must ask your attention to a third set of spectra. We produced, first of all, a continuous bright spectrum; then an interrupted bright spectrum; but what would happen if we interposed between a continuous spectrum and the light something which would take part of the light away? If we put an opaque body, we should arrest the whole of the light; but if we introduce a transparent coloured substance, we shall intercept portions of the light. Now, by properly choosing our media, we may produce interrupted spectra with black or dark lines upon them; and these are spectra of a high degree of interest. I shall exhibit one or two of the methods by which we may produce these effects. When light is transmitted through a solution of permanganate of potash without using the prism, the liquid has a splendid purple or red colour, according to the degree of dilution. We will first show the spectrum of white light, and then we will interpose the permanganate. You will see, when this solution is placed in a glass cell with flat sides so as to intercept the spectrum from the charcoal points, we obtain a certain number of bands, which occur at intervals upon the screen.

I now proceed to the examination of one of the salts of the rare metal called didymium. Nitrate of didymium and potash furnishes a solution of a very pale red colour. When this is introduced in the course of the ray you see two remarkable bands, one in the orange and the other in the green. Besides this, portions of the blue rays are also cut off. This is a spectrum of absorption produced by a liquid which has so faint a colour that it is scarcely perceptible to the naked eye, yet its spectrum is perfectly characteristic. Dr. Gladstone, who first pointed out this peculiarity of didymium, was enabled by its means to discover didymium as an impurity in other bodies previously supposed to be free from it. These two last spectra, you will observe, are absorption spectra produced by liquids. Such absorbent actions are important, as they enable us in many cases to distinguish the nature of the bodies which are held in solution. Professor Stokes has insisted particularly upon the value of studying this class of actions; and quite recently a valuable paper upon the subject has been communicated to the Royal Society by Mr. Sorby. But, interesting and important as this branch of inquiry is, it would lead us too far astray from our immediate subject, which is specially concerned with the examination of the spectra of bodies at a very high temperature, and the action upon such spectra of gaseous bodies, either at ordinary or at elevated temperatures. The phenomena with which we have at present to deal, enable us to examine the constituents of the gases in furnaces, in active volcanoes, in the fixed stars, in meteors, and in those still more enigmatical bodies, the nebulæ.

For this purpose we will now examine the absorbent action of a brownish-green coloured gas, the peroxide of chlorine. You see there are bands coming out, there being an absorption, particularly of the blue and violet portion of the spectrum, to a very considerable extent. The bands are still more marked in those portions of the spectrum which are not visible until they are received upon a fluorescent screen. The next gas which we will introduce in the same manner, interposing it exactly in the track of the ray, is the peroxide of nitrogen (the red nitrous fumes which are produced whenever a metal, such as copper or mercury, is acted upon by nitric acid). The bands in this gas are in a different portion of the spectrum. The green is almost abolished, and in the green and orange we have a variety of dark bands appearing. These bands are of particular interest because they were the first absorption bands which were observed. Sir David Brewster, who discovered them, thought he saw in them a clue to the explanation of certain bands known as Fraünhofer's lines which are observed in the sun's light. This turned out to be only a partial foreshadowing of the truth, but still the fact is interesting in the history of these discoveries.

I have now shown you absorption by two coloured gases, both of them, however, at the temperature of the air. Suppose we now take a substance which is highly heated, and then examine what will be the effect of transmitting light through a vapour of this description. For this purpose I will now place in the lamp a substance which gives a light of one colour only. Sodium, when converted into vapour, gives out light concentrated into two extremely narrow bands, very close together; these are actual mathematical lines of light which cross the spectrum in the midst of the yellow. I cannot show you these lines on the screen, for the form of the apparatus is not calculated for the production of these extremely sharp lines. As the temperature rises, the sodium becomes converted into vapour, and it will gradually become more and more brilliant until you will see that this bright line is crossed by an intense black line, showing itself upon the screen in the position which was, a few moments ago, occupied by the sodium line itself. It flickers for an instant, and then it gradually fades. Again it appears, and you may now see distinctly the

black line of the sodium thrown upon the screen. That is an experiment which, simple as it looks, is really the foundation of the whole, and therefore it is that I have taken a little more time than usual in obtaining the result. I need not apologise to you, I am sure. You are accustomed to look at these things, and to value them, not for the brilliancy of their appearance, but for their real importance with regard to the subject in hand. Now, this sodium light has, as you will observe, the power of causing a black absorption band, when light, produced at a very intense temperature, is allowed to fall upon the incandescent vapour or flame of the metal at a lower temperature. Those are the conditions under which the absorption band is seen, and the person who first pointed out the real significance of the fact was Kirchhoff. The actual fact was first observed and described by Foucault, and Mr. Stokes suggested an explanation, which turned out to be the true one; but although he divined it, he did not directly prove it by experiment, or publish it to the world, and so make it his own. Kirchhoff, however, not only saw that this sodium vapour absorbed the light of the luminous body behind it, but that in this fact lay the explanation of those remarkable dark lines in the sun's light which, ever since they were first indicated by Wollaston, and carefully examined by Fraünhofer, have been a mystery to all philosophers. The black lines of Fraünhofer are represented in this diagram, which is a repetition of the upper spectrum, *plus* a certain number of black lines which cross it at intervals. The black sodium line has a corresponding black line in the solar spectrum exactly at that part which is marked D. I say "*a* black line." It does, in fact, consist of two lines, which can be discriminated from each other by the use of telescopes of sufficient power.

Now, I desire, if I can, in a few words, to explain to you how this black line is produced. It certainly seems a remarkable thing that the addition of two lights should apparently produce darkness. We know this, however, for a fact in other cases; for light, and in some cases sound, produces the phenomenon of interference, as it is called; but this is not a true case of interference—it is a case of absorption. The spectrum of sodium has the power of absorbing only that thin line of light which it made upon the screen, just as, when we take one of these forks and hold it over the particular box which responds to it, and which absorbs its vibrations, it produces a sound; but the fork produces no sound when held over a second box of different dimensions [holding it over another box]. In the first case, we have a powerful resonance, but there is nothing perceptible from either of these other boxes. Well, this furnishes an analogy—though a rough one—to the way in which the sodium vapour acts in taking up the vibrations which are produced in that particular slice of light from the sodium, appropriating them to the actual raising of its own temperature, and then radiating them out—wholly absorbing them first, and then reradiating them.

How is it that this is a black line? In the black line, as it appears upon the screen, it is true that there is a greater amount of light than the sodium alone could produce, and it is black only by contrast. That part of the spectrum which looked black just now would have appeared bright if seen alone, but as I had a more brilliant spectrum behind it, the light of that spectrum, in falling on the screen, produced upon the eye the effect of a contrast, which led you to believe that the comparatively feebly illuminated sodium line was actually black. That is the cause of the black lines we appear to see in the spectrum of the sun, of the fixed stars, and of a variety of other lights.

I intended to say a word or two upon the composite nature of the solar spectrum before I concluded this part of our subject; but I need not dwell long upon this point, as it has already been insisted upon more than once in the theatre of this Institution. I stated just now that if we obtained the solar spectrum, and examined it—spread it out—we should have a certain amount of light, which we may represent by that band of coloured light which is seen in this diagram. If you notice, you will observe that that coloured stripe is bounded by a curved line above. This is the red end, and here it goes off into the violet. Now, this curve is the result of measurements made very carefully by Fraünhofer for the purpose of ascertaining what is the distribution of light in the different parts of the solar spectrum. A second curve traces the outline of this black mountain, which Dr. Tyndall has been working at, and is intended to indicate the distribution of heat in the spectrum. It is very important to remember that the light given by the sun is but a small portion of the force which it is radiating upon the earth. The portion of the curve filled up with black represents that part where the vibrations are least rapid. Then, when the vibrations increase in rapidity, we get red light. Still more rapid vibrations give us yellow; still more rapid give us green; then we get to the blue and violet. The principal curve in the diagram represents to the eye very roughly, but to a certain extent correctly, the distribution of heat in the visible portion of the spectrum. The heat increases in intensity as we approach to the red, and the light diminishes. The third curve represents the distribution of the chemical rays. If you allow the spectrum from the light of the electric spark taken between points of silver to fall upon the photographic surface of a collodion film, you get a very long strip of light, in which you have a series of the same sort of bands as you have already seen in the luminous portion of the silver spectrum. The vapour of silver gives us a series of interrupted bands, which exert a powerful effect in photographic experiments.

One experiment before I conclude, in order that I may show you the photographic image of the spectra obtained by transmitting a series of powerful electric discharges between wires of the four metals which I spoke of just now. First, the spectrum of silver. There you will see the image prolonged. This is the most refrangible part. The photographic image of the electric spark between wires of silver is five or six times as long as the visible spectrum obtained from silver when heated in the voltaic arc. Here is the photographic spectrum of magnesium, and here is a photograph of the spectrum of thallium. About one-tenth only of the length of any of these spectra is visible to the eye. Finally, here is the photographic spectrum of copper.

PHARMACEUTICAL SOCIETY.

Wednesday, May 15, 1867.

G. W. Sandford, *Esq.*, *President, in the Chair.*

The twenty-sixth annual general meeting of this Society was held on Wednesday, the 15th inst., when the report of the Council was received, and the Council and Audit Committee for the ensuing year were elected. The meeting then resolved itself into a special general meeting, convened for the purpose of taking the sense of the members of the Society relative to the 19th clause in the amended Pharmacy Act. This was one of the largest meetings of members ever held. Mr. Abrahams, of Liverpool, moved, and Mr. Boyce, of Chertsey, seconded, a resolution condemning the policy of applying for an amended Act when the Society was in such a prosperous state. Messrs. Pedlar, Richardson, and others thought that by admitting all chemists without examination they would be doing an injury to those members who had already passed the examinations. After a long discussion, Mr. Collins, of St. Pancras, moved, and Mr. E. Vizer, of Pimlico, seconded, the following amendment:—"That, in the opinion of this meeting, the proposed amendment of the Pharmacy Act is both wise and expe-

dient, as, by enlisting the support of those members of the trade outside the pale of the Society, the way is cleared for carrying into effect the primary objects of the Society— viz., the consolidation of the whole trade, and legislative provision for the compulsory examination of all persons entering the same after a given time. This meeting would further express its entire approval of the action taken by the Council, and pledges itself to support, by all possible means, the passage of the Bill through Parliament." Messrs. Edwards, Squire, Orridge, Morson, Savage, and Randall supported the amendment, which, after considerable discussion, was carried by a large majority.

ACADEMY OF SCIENCES.

May 20, 1867.

(From our Special Correspondent.)

M. Delaunay presented, in the name of M. Camille Flammarion, a note on a change remarked on the surface of the moon in the crater of Linnæus. It is well known that this crater has recently been subjected to an essential modification. The attention of astronomers having been called to this fact by M. Jules Schmidt, of Athens, M. Flammarion chose the moment when the sun rises at the meridian of Linnæus to study this spot. The sun, being only yet elevated a few degrees above the horizon of the crater in question, lit it up very obliquely. The slightest irregularities in the conformation of the surface were most distinctly visible. An attentive observer would remark at once that Linnæus is no more a crater; there is no exterior shadow, no shade in the centre. In its place there is only a cloudy, white, circular spot, or rather a white stain on the ground. Far from being elevated as a crater, it has a greenish colour, like the Sea of Serenity, and seems to be neither in relief nor sunken, but resembles a lake of a lighter colour than the neighbouring plain.

This crater has therefore descended to the level of the plain—fallen in—or else the plain has been raised to about the level of the crater. The interior appears also filled up, for no shadow is distinguishable, whilst smaller craters, such as A and B of Bessel, A and B of Linnæus, and those in the neighbourhood of Posidonius, show the dark shadow very perceptibly. If Linnæus had this aspect at the time when Beer and Maedler laid down their selenographic map, it would have been impossible to have indicated it as a crater. In the map constructed eight years ago by Lecouturier the height is not marked. It appears that it was very deep, ten kilometres in diameter, and that it served as a fixed point for Lorkmann and Maedler.

On May 11, the sun being more elevated, Linnæus presented the same aspect as on the evening before. The evening of the 12th was rainy; the 13th the atmosphere, being very pure, permitted the author to distinguish in the Sea of Serenity a multitude of small disseminated craters. The plain was brilliant, and Linnæus had the same relative brightness.

M. Chacornac, who observed the same things at Lyons, arrived at similar conclusions. Father Secchi, of Rome, has already presented to the Academy his own observations. It is, then, proved for a certainty that a movement has recently taken place in this region of the lunar world. The magnifying power used was 230 to 300 times.

Baron von Liebig read a note "*On an Alimentary Preparation for Replacing Human Milk for Children.*" Human milk of a person in good health contains, per cent., cascine, 3·1; sugar of milk, 4·3; butter, 3·1. Baron von Liebig concluded therefrom that woman's milk contains:—Blood-forming principles, 1 part; heat-producing principles, 3·8 parts. By mixing flour and milk in certain proportions, it is easy to compose a food in which the two nutritive principles are in the same proportion as in human milk—viz., 1 to 3·8. Cows' milk contains, on an average, 4 per cent. of cascine, 4·5 of lactose, 2·5 of butter. If we take, then, 10 parts of milk, 1 part of wheat flour, and 1 part of ground malt, we have a mixture satisfying all the necessary conditions. For preparing this the author recommends the following method:—A mixture is made of 15 grammes of wheaten flour, 15 grammes of ground malt, and 6 grammes of bicarbonate of potash; 30 grammes of water and 150 grammes of milk are then added. The whole is then heated and continually stirred until the mixture begins to thicken. It is then taken off the fire and stirred all the while. After five minutes it is boiled, and then strained through a wire or hair sieve. The ground malt necessary for this preparation is easily furnished by barley malt, obtained at any brewery. It can be ground in a common coffee-grinder, and then passed through a sieve. If this preparation is well made, it is as sweet as the natural milk; it is fluid enough, and keeps for twenty-four hours. In Germany the use of this food is very extensive, and its nutritive qualities are found to be excellent. It has a slight taste of flour or malt, to which children get accustomed—in fact, they soon prefer it to any other food.

M. Charles Robin presented on the part of the family of M. Godard, a work of this doctor entitled "Medical and Scientific Observations made in Egypt and Palestine." This *savant*, who died at Jaffa of a liver complaint contracted at Jerusalem, where he was studying leprosy, founded an annual prize of 1000 fr., already twice awarded by the Academy of Sciences.

M. Paul Thenard announced that M. Michel Perret, by an ingenious process, the result of theory and practical studies, had made a great improvement in the art of making wine. He avoids at the same time acetification, and obtains better colour and more spirit.

This paper was followed by one on chemical researches on the water found in a bronze vase at Pompeii. On the 29th of March last, while making some excavations in a house at Pompeii, a bronze cooking pot was found on an iron tripod. A cover, also of bronze, fitted exactly upon the top of the vase, so that water falling upon it could not penetrate into the interior. On the ground were found three handles, also of bronze, two of which belonged to the vase, and the other, formed of two dolphins, belonged to the cover. They had originally been soldered to the vase and cover. The vessel was found full of water. The diameter of the vase was 15 centimetres, and it was 20 centimetres high. The water was perfectly limpid, and was hardly rendered turbid by a prolonged ebullition with a feeble alkaline reaction. At the temperature of 20° C. its sp. gr. is 1·001, about that of distilled water. The quantity of fixed matters left by evaporation was 1·032 gr. per litre. The gases disengaged by ebullition consisted of air and carbonic acid. Lime and magnesia were found in it; also phosphates in a small quantity; also some traces of sulphates, and even silica and iron. There was not the slightest trace of copper.

NOTICES OF BOOKS.

Chemical Technology; or, Chemistry in its Application to the Arts and Manufactures. By Thos. Richardson, M.A., Ph.D., F.R.S.; and H. Watts, B.A., F.R.S. Second Edition. Vol. I. Part V. London: H. Baillière, 219, Regent Street. 1867.

This second edition of a well-known volume has given an opportunity for several important additions, with an announcement of the parts necessary for the completion of the series.

The work itself has already acquired imposing size, and the complete set forms in itself a library for the manufacturing chemist, who, indeed, could do without it altogether with difficulty, and would incompletely replace it as his book of reference by a great mass of

materials—such a mass, in fact, as must of necessity be consulted by competent chemists for the successful completion of a scheme like this.

The first volume is formed of five parts, each of octavo size, with from 800 to 900 pages. Parts I. and II. contain Fuel and its Applications; Part III., Acids, Alkalies, and Salts; Part IV., Aluminium, Sodium, Phosphorus, Lucifer Matches, Borax, Artificial Mineral Waters, Gunpowder, Gun-cotton, Fireworks, &c.; and the present volume, Part V., Prussiate of Potash, Oxalic Acid, Tartaric Acid, Tartrates of Potash, and Citric Acid, with appendices presently to be noticed. We have thus four handsome books forming Volume I. Volume II. contains Glass, Alum, Potteries, Cements, Gypsum, &c., &c. Volume III., Food generally, Bread, Cheese, Tea, Coffee, Tobacco, Milk, Sugar.

These three volumes are all that have at present appeared; they form six octavo books of large size, illustrated with woodcuts, plates, engravings, and, in the last volume, coloured plates.

The book itself is rich in passages we should like to quote were it not for their length. There is, however, one value connected with a work of this kind which ought to be pointed out. Most young chemists, after passing through the routine course of their scientific education, feel somewhat at a loss to know in what direction to turn their experimental energies, so as to obtain a prospect of some return for their trouble. As we stated in these pages a few weeks ago, it often happens that a difficulty is found in carrying out some manufacture which could easily be overcome, by a short investigation, by a competent chemist; and, indeed, in many cases a difficulty which appears insuperable to the manufacturer, would prove a mere *bagatelle* to the chemist. The difficulty, however, is for the young experimentalist to know what are the problems in industrial chemistry which require solving. In this respect the present series of Chemistry Applied to the Arts and Manufactures constitutes a very mine of wealth. As an illustration, we learn that with regard to the determination of the commercial value of tartars, it is a point of the utmost importance that some method should be devised for ascertaining correctly the quantity of tartaric acid present, which is now merely deduced from the quantity of potash found.

That this method is by no means an accurate one may be seen from the three following analyses of the same sample, viz:—

Tartaric acid present as bitartrate of potash	70·15	69·10	72·25
Tartaric acid present as tartrate of lime	3·35	3·30	3·75
Total crystallised tartaric acid, per cent.	73·50	72·40	76·00

This is so urgent a matter, that one of the largest and most distinguished manufacturers of tartaric acid has expressed his willingness to give 100*l.* as a reward to any one who would discover a satisfactory method of determining, directly, the quantity of crystallisable tartaric acid present in tartars, in a sufficiently ready manner to be applicable to commercial analysis. This is only one of the many chemical problems to be met with throughout the work, the solution of which would be attended with considerable profit.

The following are announced as in preparation to complete the work:—Vol. IV. devoted to Liquid Food, Ales, Wines, Spirits, &c.; V. and VI. to Textile Manufactures, Cotton, Wool, Silk, &c.; VII. to the Manufacture of Leather, Gutta Percha, &c.; VIII. to Manufacture of Paper, &c.; IX., X., XI., to Metallurgy and Chemistry of the Metals; XII. to the Manufacture of Colours, Oils, and Varnishes. These will complete an elaborate and exhaustive work, which English chemists will mention with pride, as a proof of the repute in which chemistry is beginning to be held in our country. It seems that no space will be given separately to the consideration of the preparation of medicinal substances in a pure form, such as morphia, chloroform, &c.

As regards this present edition of the volume under notice, no one will doubt the wisdom of the retention of the older notation of the former one, which is still most applicable to the wants of the manufacturer, who cannot be expected to be well acquainted with the newer views held in 1867. The next edition will be in time for those of a younger generation now pupils at various laboratories.

Of the 900 pages of this part, upwards of 700 are devoted to the various appendices. Appendix A consists of additions to the various chapters of Vol. I., parts iii., iv., and v., first edition, and brings the report up to the present time; nearly 300 pages are devoted to this part of the work. Appendix B contains abstracts of specifications of patent inventions relating to materials and processes described in those same parts; Appendix C (of the greatest value), tables connected with the processes described in the former parts; Appendix D, documents relating to the Patent Laws, appearing at a very opportune time. A casual glance will show a great part of the value of all these appendices, but Appendix C is so important, and would be so useful for constant reference, that we would urge a publication of it separately; it would form a volume more easy for constant reference than in its present the form. Lastly, we think that the whole of the additions to the first edition, which form the bulk of the book, ought with justice to be prepared also in a separate form. Possessors of the first edition should not be expected to buy the whole volume, part of which they already possess. The same reason should have weight with the publishers, when the time comes for newer editions from time to time. If this were promised, the different parts would have a lasting value even to a greater extent than at present; besides this, the latest information could be more frequently supplied, to supply a more extensive demand. The plates, five in number, are excellent; two of them consist of tables and scales, the other three of apparatus, &c. It would have been better if the paper for these had been of a stronger kind, or mounted on some material to make them more durable for frequent reference. We commend a consideration of this point to Messrs. Richardson and Watts for discussion in the forthcoming volumes relating to textile manufactures and the manufacture of paper.

"Chemical Technology," clearly and accurately written, neatly sent to press, and very moderate in price, may justly be a source of pride to the authors, the publisher, and the profession generally.

CONTEMPORARY SCIENTIFIC PRESS.

[Under this heading it is intended to give the titles of all the chemical papers which are published in the principal scientific periodicals of the Continent. Articles which are merely reprints or abstracts of papers already noticed will be omitted. Abstracts of the more important papers here announced will appear in future numbers of the Chemical News.]

Annales de Chimie et de Physique. March, 1867.

NOTICES OF PATENTS.

2077. *Making Caustic Soda from Common Salt, by the Action of Lead or its Oxide, with After Recovery of the Lead for further Use.* S. Rowbotham, Penkett, near Warrington. August 14, 1866.

The sodic chloride is either fused with the lead or mixed with plumbic oxide and water until decomposition takes place. Heat may or may not be necessary; the whole is kept moist by steam. The caustic soda is separated by lixiviation. The plumbic chloride left is then exposed to the action of oxygen with heat, or steamed to recover the lead or its oxide. The lead is further to be purified by the action of charcoal.—Patent abandoned.

2095. *Coating and Recovering Metals from Chlorides and other Solutions of Metals.* J. Webster, Birmingham. August 15, 1866.

Chiefly applied for using the zinc chloride in the flux used in the pots for galvanising iron. This is boiled in a cast-iron vat; when the temperature reaches 600° Fahr., scraps of tin or wrought iron from other manufactures are added. The vat has a longitudinal partition, which is a grating or perforated plate to allow of free diffusion; in one half the scrap tin or iron is placed, in the other articles that require a coating of zinc or tin. In this also scrap materials must be placed and pressed on the bottom of the vat by another perforated iron plate for the hydrogen gas to escape. Copper, brass, &c., by such a coating of zinc or tin, are protected from atmospheric action.

Communicated by Mr. Vaughan, F.C.S., Patent Agent, 54, Chancery Lane, W. C.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

1107. C. Crockford, Holywell, Flintshire, "Improvements in obtaining useful products from certain materials produced in the process of galvanising or coating iron with zinc."—Petition recorded April 13, 1867.

1118. The Rev. J. Oakden, St. Stephen's Parsonage, Congleton, and J. Picking, Dane Row, Buglawton, Congleton, "A new or improved enamel for enamelling metals and stones, to prevent rust, corrosion, and incrustation." April 15, 1867.

1190. J. H. Johnson, Lincoln's Inn Fields, Middlesex, "Improvements in the treatment of peat, and in the manufacture of peat charcoal, and in the machinery or apparatus employed therein." A communication from A. Figge, Hanover.—April 24, 1867.

1198. C. E. Brooman, Fleet Street, "A new or improved process of destroying vegetable matters in wools, noils, woollen waste, and rags." A communication from C. Schaller, Bischweiler, France.

1200. C. E. Brooman, Fleet Street, "A new or improved process of preserving meat, fish, and other substances." A communication from F. Cirio, Turin, Italy.—April 25, 1867.

Notices to Proceed.

935. J. Bird, Seymour Street West, Connaught Square, Middlesex, and J. Bird, Laurence Pountney Hill, London, "Improvements in the manufacture of artificial fuel."—Petition recorded March 29, 1867.

952. W. E. Newton, Chancery Lane, "An improved process for manufacturing ice, and for other refrigerating purposes." A communication from T. S. C. Lowe, New York, U.S.A.—March 30, 1867.

1042. W. Henderson, Glasgow, "Improvements in oxidising minerals, ores, and metals; in reducing oxides of metals; in separating certain metals from each other; in kilns, furnaces, or other apparatus for these purposes; and in the treatment of the products obtained therefrom."—April 6, 1867.

1153. W. Harrison, Wharton Green, Winsford, Cheshire, "An improved method of consuming smoke in furnaces."—April 20, 1867.

CORRESPONDENCE.

Transparency of Red-hot Metals.

To the Editor of the Chemical News.

Sir,—One of the contemporaries, though not a strictly scientific periodical, of your valuable paper, calls attention to a highly curious and startling fact observed and communicated by the reverend and highly eminent *savant*, Father Secchi, of Rome, concerning the transparency of iron while red-hot. The fact that iron, steel, and also platinum and copper, are transparent while at a bright red heat, has been known long since not only to practical engineers, but, as regards iron, steel, copper, and platinum, to workers in these metals. The account given of the manner in which the excellent member of an eminent society found out this property of iron is as follows:—The reverend Father had ordered a strong iron tube to be made. As it was intended for an apparatus requiring a vacuum, it was essential that this tube should be perfectly air-tight; and as Father Secchi had some doubts about its soundness in this respect, in order to set these at rest the tube was made red-hot and taken into a dark place, when Father Secchi clearly perceived through the iron, which was half a centimetre thick, a crack inside the tube, and which did not reach to the outer surface. It is rather curious that the fact of the metals above alluded to, to which I have reason to believe that gold may be added, becoming transparent at red heat should have escaped the notice of scientific men. It requires, however, a good bright red heat; but the transparency of the metals is evident thus even in daylight, as I know from my own experience while working in an engineering establishment attached to a large sugar refinery, now many years ago.

I am, &c. A. Adriani.

[The above statements are so much at variance with all previous ideas on the subject, that much stronger evidence will be required before the transparency of red- or white-hot metals can be accepted as proved.—Ed. *C. N.*]

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Cyanin (C = 12).—Dr. G. Nadler and Dr. V. Merz. The cyanin, or chinoline blue, which forms the subject of this paper, was prepared from tolerably pure chinoline, and was, therefore, an amylchinoline derivative. Chinoline blue, or iodocyanin, $C_{28}H_{35}N_2I$, is almost insoluble in ether and cold water, rather soluble in hot water, sparingly so in cold alcohol, and very soluble in hot alcohol; the green crystals melt and lose water at 100°; their solution in alcoholic solution of nitric acid is precipitated by argentic nitrate. Iodocyanin is capable of uniting with one or two molecules of acids; its solution in chlorhydric acid, if allowed to evaporate spontaneously in presence of lime, deposits colourless crystals, $C_{28}H_{35}N_2I,2HCl$, which lose HCl at 90—100°. A warm alcoholic solution of iodocyanin digested with fresh argentic oxide gave cyanin $C_{28}H_{36}N_2O$. A chlorhydric acid solution of cyanin precipitated by ammonia, or an alcoholic solution of iodocyanin digested with argentic chloride, gives chlorocyanin, $C_{28}H_{35}N_2Cl$, easily soluble in alcohol and hot water, sparingly so in ether and cold water, combining with acids to form colourless compounds. Nitrato-cyanin was prepared by precipitating an alcoholic solution of iodocyanin, acidulated with nitric acid, with argentic nitrate; it is slightly soluble in ether and cold water, easily so in alcohol; its formula is

$$\left.\begin{matrix}C_{28}H_{35}N_2\\NO_2\end{matrix}\right\}O;$$

it combines with acids to form colourless bodies; treated with ammonic sulphide at 100°, $C_{56}H_{68}N_4S_3O_2$ was obtained. Iodocyanin, heated with concentrated sulphuric acid, gave sulphatocyanin—

$$\left.\begin{matrix}2C_{28}H_{35}N_2\\SO_2\end{matrix}\right\}O_2,$$

which, air-dried, is a light brown body, which decomposes, without melting, at 120°. From it other similar bodies, such as oxalocyanin,

$$\left.\begin{matrix}2C_{28}H_{35}N_2\\C_2O_2\end{matrix}\right\}O_2,$$

are obtainable.

It appears from the above that cyanin is capable of forming with acids three kinds of bodies—the monacid bodies are intensely coloured, the triacid compounds are colourless and easily decomposed, giving rise to diacid compounds. All the coloured compounds are unstable in sunlight.—(*Journ. prakt. Chem.* c. 129.)

Oxalohydroxamic Acid (C=12).—H. Lossen. This is one of two acid bodies formed by the action of hydroxylamine on ethylic oxalate; it is very difficultly soluble in cold water, but crystallises from boiling water; it explodes at 105°; dried over sulphuric acid it contains $C_2H_4N_2O_4$, which formula, however, may need to be tripled. Its salts are generally insoluble, or sparingly soluble, in water, and explode if heated to 130° or 180°, or if put into concentrated sulphuric acid. The constitution of the acid is probably expressed by

$$\left.\begin{matrix}C_2O_2\\(HO)_2\\H_2\end{matrix}\right\}N_2$$

(*Zeitschr. Chem.*, N. F., iii. 129.)

Sarcolactic Acid.—O. Schultzen. The urine of men or animals that have been poisoned by phosphorus, when the poisoning has reached the stage of colouring the skin, contains large quantities of this acid. To extract it the urine was evaporated to syrupy consistence, the alcoholic extract of the syrup was evaporated, the residue was treated with sulphuric acid and ether, the ether was decanted, and the substance left on its evaporation was purified by a small quantity of plumbic acetate freed from lead by sulphhydric acid, and from acetic acid by evaporation; sarcolactic acid remained, which was identified by analysis of the zincic, cupric, and calcic salts.—(*Zeitschr. Chem.*, N. F., iii. 138.)

Bichlorsulphobenzide (C=12).—R. Otto. This body—

$$\left.\begin{matrix}C_6H_4Cl\\C_6H_4Cl\end{matrix}\right\}SO_2$$

is easily obtained by the action of chlorobenzol on sulphuric anhydride. It is insoluble in water, and crystallises from hot alcohol in long white needles, melting at 140—141°.—(*Zeitschr. Chem.*, N. F., iii. 143.)

Chlorbenzolsulphuric Acid (C=12).—R. Otto. This acid is a by-product in the preparation of bichlorsulphobenzide. It is obtainable in long white asbestos-like deliquescent needles, fusible in the water oven, easily soluble in water and alcohol, insoluble in ether and benzol. It is monobasic—

$$\left.\begin{matrix}C_6H_4Cl\\SO_2\\H\end{matrix}\right\}O.$$

Its salts are mostly soluble in water, and may be heated to 200° without decomposition. The sodic, potassic, calcic, baric, plumbic, cupric, and ethylic salts are described.

The chloride

$$\left.\begin{matrix}C_6H_4ClSO_2\\Cl\end{matrix}\right\}$$

is easily obtained by acting upon sodic chlorbenzolsulphate with phosphoric pentachloride. It is soluble in ether, benzol, and alcohol; insoluble in water. It forms magnificent four-sided rhombic tables, often of considerable dimensions. It melts at 50—51°. With alcoholic solution of ammonia, sulphochlorbenzolamide is formed,

$$\left.\begin{matrix}C_6H_4ClSO_2\\H_2\end{matrix}\right\}N,$$

crystallising from water in four-sided rhombic pillars of large size. It melts at 143—144°. By acting on chlorbenzolsulphuric chloride with zinc and sulphuric acid, chlorphenylsulphhydrate is obtained,

$$\left.\begin{matrix}C_6H_4Cl\\H\end{matrix}\right\}S,$$

which forms superb crystals, melting at 53—54°, distilling undecomposed, insoluble in water, soluble in ether and alcohol. It combines with mercuric chloride to form a compound insoluble in boiling water or alcohol, and gives with nitric acid chlorphenylic sulphide,

$$\left.\begin{matrix}C_6H_4Cl\\C_6H_4Cl\end{matrix}\right\}S_2,$$

insoluble in water, easily soluble in hot alcohol, ether, or benzol, melting at 71°, and distilling undecomposed.

Chlorbenzolsulphurous acid results from chlorbenzolsulphuric chloride under the influence of sodium amalgam. It crystallises in small rhombic needles, easily soluble in hot water and alcohol, melting at 88—90°. The sodic, calcic, plumbic, and ethylic salts are described. Its formula is

$$\left.\begin{matrix}C_6H_4Cl\\SO\\H\end{matrix}\right\}O.$$

—(*Zeitschr. Chem.*, N. F., iii. 144.)

Organic Acids, a New Series of (C=12).—P. Griess. Diazobenzoic perbromide (*Ann. Chem. Pharm.* cxxxv. 121), in solution of ammonia, decomposes with formation of $C_7H_5N_3O_2$, easily soluble in alcohol and ether, difficultly so in boiling, insoluble in cold water, melting at about 160°; it forms definite salts. The argentic salt is a white amorphous precipitate, $C_7H_4AgN_3O_2$. Analogous acids are formed by the action of ammonia on diazodracylic and diazosalylic perbromides. Diazoanissic and diazohippuric perbromides react in a similar manner. The reaction is therefore general.—(*Zeitschr. Chem.*, N.F., iii. 164.)

Ethyl- and Diethyl-benzol, Products of Oxidation of (C=12.)—R. Fittig and J. König. Ethylbenzol is easily oxidised by dilute nitric acid, benzoic acid with traces of a nitro-acid being produced. Monobromethyl-

benzol gave by oxidation bromdracylic acid identical with that obtained by Hubner and Philipp from bromtoluol. Diethylbenzol, treated with potassic dichromate and sulphuric acid, gave terephthalic acid, but, if oxidised with dilute nitric acid, an acid isomeric with xylylic acid is produced, and which may be called ethylbenzoic acid,

$$C_6H_4 \begin{cases} CO_2H \\ C_2H_5. \end{cases}$$

It crystallises from water or alcohol, and melts at about 110°. The baric, calcic, argentic, and cupric salts were analysed. This acid differs from all others of similar constitution. It may be regarded as bromdracylic acid, in which Br is replaced by ethyl; and it will perhaps be identical with an acid which Kekulé hopes to obtain by the action of bromethylbenzol on sodium and carbonic dioxide. The production of bromdracylic acid above mentioned proves that in bromethylbenzol the same H atom in the benzol residue is replaced by bromine, as is the case in bromtoluol.—(*Zeitschr. Chem.*, N. F., iii. 167.)

Opium, Alkaloids of: their Separation.—M. Kubly. The substance to be examined is extracted with benzol; narcotine, papaverine, thebaine, and codeine, are dissolved. Amylic alcohol dissolves morphine from the residue, and alcohol will extract narceine, if present in what is left undissolved by the two former solvents. To separate the four alkaloids soluble in benzol, cold amylic alcohol is used, which dissolves codeine; very dilute acetic acid will then extract papaverine and thebaine from the narcotine which remains. Finally, thebaine is precipitated from the sulphuric acid solution of papaverine and thebaine by bismuthic iodide in potassic iodide solution, papaverine remaining in solution.—(*Pharm. Journ. Russ.* Nov. 1866, 457.)

MISCELLANEOUS.

Quinine.—The *Homeward Mail* reports a singular affair which has just occurred at Calcutta. Under the Indian Patent Act, every exclusive privilege must cease if the Governor-General of India in Council shall declare that the same is generally prejudicial to the public. This has accordingly been done in the case of a petition filed by W. G. M'Ivor, who wishes for a patent for an alleged new invention for producing and preparing the different species and varieties of cinchona bark for the manufacture of quinine, quinidine, cinchonidine, and other alkaloids.

Alum Crystallisations over Fresh Flowers.—Make baskets of pliable copper wire, and wrap them with gauze. Into these tie to the bottom violets, ferns, geranium leaves, chrysanthemums—in fact, any flowers except full-blown roses—and sink them in a solution of alum of one pound to the gallon of water, after the solution has cooled, as the colours will then be preserved in their original beauty, and the crystallised alum will hold faster than when from a hot solution. When you have a light covering of distinct crystals that cover completely the articles, remove carefully, and allow them to drain for twelve hours. These baskets make a beautiful parlour ornament, and for a long time preserve the freshness of the flowers.—*W. P. Creecy*, in the *Am. Journ. Pharmacy*.

Estimation of Silver in a Metallic State.—According to M. Classen, silver is wholly precipitated by cadmium; when dealing with a nitric solution of silver, evaporate to dryness in the presence of sulphuric acid, dissolve the sulphate of silver in boiling water, plunge into it a plate of cadmium, and the reduction of the silver takes place at once. The silver is deposited in a compact mass, easily washed with water; as it may contain a little cadmium, boil it in the acid liquid until no hydrogen escapes; wash it until the water contains no sulphuric acid; then dry, and calcine; the silver, at first a black grey, takes the metallic lustre; it may then be weighed:—the results are very exact.

NOTES AND QUERIES.

Map Varnish.—Sir,—J. S. will find that he can make a very good varnish for covering over architectural and mechanical drawings, maps, &c., by dissolving one pound of white shellac, a quarter of a pound of camphor, and two ounces of Canada balsam in one gallon of alcohol.

Map Varnish.—Sir,—I beg to place the following recipe at the service of "J. S.," who wishes to know how to prepare a good quick-drying map varnish:—Thin down with turpentine Canada balsam, and add one-fourth of the bulk of quick-drying pale copal varnish; lay on smoothly with a flat camel-hair brush, and let the map lie flat for a few hours.—Thos. Bournes.

Artificial Teeth.—In reply to the inquiry from F. T., Leeds, in our last number, we have received several letters. They have been forwarded as requested.

Chinese Blue.—Sir,—Will you oblige me by notifying that you wish to receive communications for a subscriber on the subject of Chinese blue from the same or others who replied to R. H. W., of Manchester? Information of value would be paid for.—Wm. Schofield.

Palm Oil.—Sir,—If any of your correspondents will inform me how much chrome is necessary to bleach a cwt. of palm oil, they will confer a favour on yours, &c., Milo.

Santonine.—Sir,—Can any of your readers favour me with some good directions for mounting santonine for the microscope so as to obtain good polarising crystals?—F. Cooper.

Letters are waiting at our Office for F. T., Leeds; R. E. B., Manchester; H. P. Meaden; J. K. M.; Manufacturer.

ANSWERS TO CORRESPONDENTS.

*** In publishing letters from our Correspondents we do not thereby adopt the views of the writers. Our intention to give both sides of a question will frequently oblige us to publish opinions with which we do not agree.

Vol. XIV. of the Chemical News, containing a copious Index, is now ready, price 11s. od., by post, 11s. 6d., handsomely bound in cloth, gold-lettered. The cases for binding may be obtained at our Office, price 1s. 6d. Subscribers may have their copies bound for 2s. 6d. if sent to our Office, or, if accompanied by a cloth case, for 1s. Vols. I., II., and VII. are out of print. All the others are kept in stock. Vol. XV. commenced January 4, and will be complete in 26 numbers.

*** Owing to press of matter, we are obliged to defer an article by D. Forbes, F. R. S., on the Blowpipe, a paper by Professor Church on the Benzol Series, a verbatim report of Dr. Odling's lecture delivered at the Royal Institution last Friday, and several reviews, letters, &c. Up to the time of going to press the Abbé Moigno's weekly letter had not arrived.

James Y.—The term iodide of calomel is retained in American pharmacy for a mixture of iodide and chlorides of mercury, prepared by mixing iodine with calomel. According to the same barbarous nomenclature, there is a biniodide of calomel.

Butter.—You are mistaken in supposing that only rancid butter contains butyric acid. Fresh butter contains a compound of butyric acid with glycerin, which is inodorous; and it is to the decomposition of this compound on standing, by which butyric acid is set free, that the flavour of rancidity is due.

A Student will find full information on the subject of the atomicity of radicals in Wurtz's "Introduction to Chemical Philosophy," page 104, *et seq.*

M. R.—The office where the hot-air engine, described in our last number, may be seen, is 531, Oxford Street.

Kappa.—You will find all you require in Griffin's "Chemical Handicraft."

Constant Reader.—Are you sure you deserve that name? An article giving all the information you inquire for appeared only three numbers ago.

P. McPherson.—Heavy hydrocarbon oils containing no naphtha are convertible into oils of the naphtha series under the action of heat.

The Chemical Society.—One who has been on the Council; A Blackball; F. C. S.; A Country Member; F. J., Wolverhampton; and others.—We think no good will be gained by continuing the discussion. The matter is occupying the serious attention of the Council, and our correspondents may rest satisfied that the decision at which they arrive will best serve to place matters on a permanent healthy footing.

An Old Subscriber.—The lecture referred to is published in the *Journal of the Chemical Society*. Richardson and Watts's "Technology" gives an excellent account of the alkali manufacture.

Communications have been received from D. Forbes; S. Mellor; H. Gillman; C. W. Heaton; Sir B. C. Brodie; G. Foord; Clayton and Co.; F. Barnes; O. Solomon; M. Williams; W. Johnstone; Professor Angelo Pavesi; C. F. Burnard (with enclosure); Robert Bell (with enclosure); J. H. Swindells (with enclosure); William Allen; James Kayen; Thomas Bournes; H. Sugg; W. Perkin; A. H. Church.

Books Received.—"On a New Process for Preparing Meat for Weak Stomachs," by W. Marcet, M.D., &c.; "Shaw's Medical Remembrancer," by Jonathan Hutchinson, F.R.C.S.

IDEAL CHEMISTRY.

On Thursday next the Fellows of the Chemical Society will assemble at Burlington House to hear a lecture by Sir Benjamin Brodie on the new Chemical Calculus. The subject is perhaps the most abstruse which has ever been brought before the Society, and it has, therefore, been considered advisable for us to give in the present number a slight outline of the methods of reasoning adopted by the learned author, as set forth in the paper* which has just appeared in the *Philosophical Transactions*.

The memoir, of which the first part is the subject of this article, will mark a new epoch in that branch of chemical science which relates to the symbolic expression of facts. The complete paper is not yet published. The present part, which was read before the Royal Society on May 3, 1866, when it attracted the liveliest attention, and some little discussion from the chemists present, relates to the construction of chemical symbols. In the second part the author proposes to treat of the theory of chemical equations, which is intimately connected with the general processes of chemical reasoning, and especially with the consideration of the nature of that event which is termed a chemical change, of which a new analysis will be given founded on its symbolic expression. In the third part it is intended to consider the principles of symbolic classification, and the light thrown by this method upon the origin and nature of the numerical laws which limit the distribution of weight in chemical change.

The author mainly confines himself at present to the discovery of a system of symbolic expressions by which the composition of the units of weight of chemical substances may be accurately represented, and which may hereafter be employed for the purposes of chemical reasoning. This problem is of a perfectly real nature, admitting, where the experimental data are adequately supplied, of only one solution; and the discussion of this question involves the consideration of the fundamental principles of symbolic expression in chemistry.

In the first section, considerable attention is devoted to the definitions, and the various terms used have definite significations attached to them. "Ponderable matter" and "a chemical substance" require no explanation, but the expression "a weight" is used in a special sense. In this discussion every chemical substance, simple or compound, is exclusively regarded as a *weight* of matter. Its form, condition, or state is disregarded, and the only property with which the chemist has here to do is the transformation of the weights of matter, and the laws of the composition and resolution of these weights. The term *a weight* is used, therefore, in a concrete sense, as when we speak of "a box of weights," and call one of the pieces of metal in the box "*a weight*" of platinum or brass. In just this sense, Sir Benjamin Brodie speaks of *a weight* of water, of oxygen, of sulphur, &c., excluding all other forces but that of gravitation.

A "single weight" is a weight of any portion of matter regarded as one object. The matter making up this weight may be simple or compound, and, if the latter, chemically combined or not. So long as it is considered as one object, it is a single weight.

A "group of weights" is constituted of any number of single weights.

Between two portions of ponderable matter (two "weights") there may be *equality* and *identity* as regards weight. These terms require fuller explanation. Take a *weight* of water—a gramme, for instance—and apply heat to it; it increases in bulk; it becomes a gas; and at a still further elevation of temperature it is resolved into its components, oxygen and hydrogen. But throughout all these profound physical and chemical changes, its action on the balance does not vary. Now, there is the relation of *equality* of weight between a gramme of water and a gramme of oxy-hydrogen gas, as there is between a gramme of water and a gramme of lead. But the gramme of water is connected with the gramme of its component gases by another relation, that of continuity of existence, or *identity*, which does not exist between the gramme of water and the gramme of lead.

A compound weight is here defined as a single weight of which the whole is identical with two or more weights. Such weights are termed the components of the compound weight, which is said to be composed of them. A "simple weight" is a weight which is not compound—that is, which has only one component.

It is necessary to select a "unit of ponderable matter" which may serve as the common measure of those chemical properties which it is desired to investigate, and in this investigation the "unit" is defined as that portion of gaseous ponderable matter which occupies the volume of 1000 c.c. at 0° C., and a pressure of 760 m.m. of mercury. This volume is called the "unit of space," and the weight of a unit of hydrogen is selected as the standard. The weights of other units of matter can therefore be expressed absolutely in grammes, or relatively in reference to the standard unit of hydrogen.

When a compound weight (*e.g.*, a weight of water) is resolved into its component weights (*e.g.*, a weight of oxygen and a weight of hydrogen), the weight is said to be "distributed." The same expression is used in reference to the converse operation of synthesis. The meaning of the term "undistributed weight" follows from the above. A distributed weight is necessarily a compound weight, and an undistributed weight must be regarded, in respect to the events under consideration, as simple, although under other circumstances it might prove to be a compound weight.

A chemical operation is defined as an operation performed on the unit of space of which the result is *a weight*. These chemical operations are represented by symbols $x, y, \ldots$. The symbol + is the symbol of the operation by which one weight is added to another to constitute with it one group. The symbol − represents the removal of a weight from a group of weights. The symbol = is the symbol of identity. The symbol $x + y$ represents a group constituted of the two weights A and B; $x + x$, or $2x$, is the symbol of two weights A; and $x - y$ is the symbol of the weight A without the weight B. The symbol o is the symbol of a group in which no weight appears, and which has had its origin in the several performances of the operations x and $-x$; so that $x - x = o$, and $o + x = x$. The symbols +, −, and = are here used in a sense analogous to their arithmetical meaning. No uniform interpretation has hitherto been attached to them in chemistry.

But the most important feature of the method is the introduction of the symbol xy as the symbol of a compound weight, of which two portions of matter, say A and B, are the component weights. This symbol indicates that we are to perform the operation y upon the unit of space, and then to perform successively upon

* "*The Calculus of Chemical Operations; being a Method for the Investigation, by Means of Symbols, of the Laws of the Distribution of Weight in Chemical Change,*" by Sir Benjamin C. Brodie, Bart., F.R.S., Professor of Chemistry in the University of Oxford.

that *same* unit the operation x, in which respect it differs from the symbol $x+y$, which indicates that the operations are to be performed upon distinct units, the results being different, according as the operations are performed *successively*, *jointly*, *severally*, or *collectively*. The symbol xy is the symbol of the *successive* operations x and y; (xy) represents their *joint* operations; $x+y$ represents them operating *severally*; and $(x+y)$ represents the same operations operating collectively. We can thus express with accuracy the various ways in which we conceive of the existence of the same ponderable matter.

The symbol 1 is necessarily contained as a common factor in every chemical symbol, and is the symbol of the common subject of operation, the unit of space. But the unit of space, as above explained, is space without weight, and the symbol 1 is therefore the symbol of "no weight." It is therefore inferred that $0=1$. This equation may at first sight appear paradoxical; it need not, however, be a matter of surprise that in the chemical calculus we should have two symbols for "no weight," since in that system the same ponderable matter may be denoted by xy and $x+y$. These different symbols are necessary, as representing the different ways the "weight" or the "no weight" has been obtained. Similarly, the symbol ∞ is to be interpreted as the symbol of the ponderable universe regarded as a whole, and the symbols 1 and ∞ represent in the calculus of chemistry the limits between which the values of all other symbols are comprised.

Now, according to the definition given of chemical identity, two weights are said to be identical which consist of the same weights; hence the weight (or matter) of which xy is the symbol is identical with the weight (or matter) of which $x+y$ is the symbol; and

$$xy=x+y.$$

This equation is the fundamental equation of the Calculus, and from it the properties of the symbols are derived.

After a discussion of the fundamental chemical equations, the symbols of simple weights (which are termed prime factors), and the construction of chemical equations from the data afforded by experiment, the author proceeds to the symbols of the units of chemical substances. One hypothesis is assumed, and that is that the unit of hydrogen is a simple weight. The symbol of this "weight" is expressed by the letter α. The absolute weight of the portion of ponderable matter thus symbolised—that is to say, of 1000 c.c. of hydrogen at 0° C. and 760 m.m. pressure—is 0·089 grm. This is identical with the "crith" of Dr. Hofmann. It is subsequently shown that the units of the elements mercury, zinc, cadmium, and tin may be symbolised in an equally simple manner. The author employs letters of the Greek alphabet as symbols of simple weights. Speaking of this, he says, "It is a mistake to confuse the objects of a symbolic system with those of a 'memoria technica,' and I am inclined to believe that a purely accidental distribution of letters among the weights to be expressed would be the best. In the selection here made, however, I have not proceeded rigidly upon this principle, a certain reminiscence of the name being retained in the symbol, as for example the ξ of *ὀξύς*, the θ of *θεῖον*, the χ of *χλωρός*, and the δ of *ὑδράργυρος*. Facility of writing and reading the symbols is, however, far more important than any aid to memory which can be thus afforded, and these points are to be mainly considered. The unit of hydrogen, which occupies a peculiar position as the 'modulus' of the system, is indicated by a special symbol α."

It is known by experiment that 2 units of water can be decomposed into 2 units of hydrogen and 1 unit of oxygen. Now, let

$\alpha^m\xi^{m_1}$ = symbol of the unit of water,
α = symbol of the unit of hydrogen,
$\alpha^n\xi^{n_1}$ = symbol of the unit of oxygen,

where α and ξ are the symbols of simple weights, and m, m_1, n, n_1 positive integers. Then

$$2\alpha^m\xi^{m_1}=2\alpha+\alpha^n\xi^{n_1}$$

To this is attached the condition that

$$w(\alpha)=1,$$
$$m+m_1w(\xi)=9;$$

from the fundamental equation

$$(\alpha^m\xi^{m_1})^2=\alpha^2\alpha^n\xi^{n_1},$$

whence

$$2m=2+n \text{ and } 2m_1=n_1.$$

Selecting from the possible solutions of these equations the minimum solution as both necessary and sufficient to satisfy the condition of the equation, we have

$$m=1,\quad n=0,$$
$$m_1=1,\quad n_1=2,$$

which give

Symbol of water, $\alpha\xi$;
Symbol of oxygen, ξ^2;

the relative weights corresponding to the prime factors α and ξ are

$$w(\alpha)=1,$$
$$w(\xi)=8,$$

the equation being thus expressed:—

$$2\alpha\xi=2\alpha+\xi^2.$$

The following table is given of the combinations of the prime factors α and ξ:—

Name of substance.	Prime Factors.	Absolute weight in grammes.	Relative Weight.
	α	0·089	1
	ξ	0·715	8
	Symbol.		
Hydrogen . . .	α	0·089	1
Oxygen	ξ^2	1·430	16
Water	$\alpha\xi$	0·805	9
Peroxide of hydrogen	$\alpha\xi^2$	1·520	17

By a similar process of reasoning, starting from the ascertained facts that the density of sulphur vapour is 32, that of hydrogen being 1, and that the ponderable matter of 2 units of hydrogen is identical with the ponderable matter of 2 units of hydrogen and 1 unit of sulphur, it is shown that the symbol of sulphur is θ^2, and that of sulphuretted hydrogen $\alpha\theta$. The symbol of sulphuric acid $\alpha\theta\xi^4$, and that of pentathionic acid $\alpha\theta^5\xi^6$. Similarly, selenium is symbolised as λ^2, seleniuretted hydrogen becoming $\alpha\lambda$.

In the case of chlorine, which may be taken as the representative of another group of elements, it is ascertained that 2 volumes of hydrochloric acid can be decomposed into 1 volume of hydrochloric acid and 1 volume of chlorine.

Hence, putting $\alpha^m\chi^{m_1}$ as the symbol of the unit of hydrochloric acid, and $\alpha^n\chi^{n_1}$ as the symbol of the unit of chlorine,

$$2\alpha^m\chi^{m_1}=\alpha+\alpha^n\chi^{n_1},$$

and

$$(\alpha^m\chi^{m_1})^2=\alpha\alpha^n\chi^{n_1};$$

whence

$$2m=1+n$$
$$2m_1=n_1$$

and

$$m=1, \quad m_1=1$$
$$n=1, \quad n_1=2,$$

a minimum.

Since the density of hydrochloric acid is 18·25, we have to determine the absolute weight of the simple weight χ,

$$m+m_1w(\chi)=18{\cdot}25,$$

whence

$$w(\chi)=17{\cdot}25,$$

which gives the

Symbol of hydrochloric acid $\alpha\chi$,
Symbol of chlorine . . $\alpha\chi^2$.

We can only briefly allude to the discussion of the symbols of carbon, silicon, and boron. Owing to the impossibility of ascertaining the vapour densities of these elements by direct experiment, their symbols cannot be determined in an analogous manner to those of the preceding elements; but inasmuch as we are able to construct numerous chemical equations which connect the vapour densities of carbon, silicon, and boron with known vapour densities, we are able to determine from these, within certain limits, the symbol of the elements themselves.

From such data as these it is rendered very probable that the symbols of carbon, silicon, and boron are respectively of the terms

$$\kappa^\nu, \ \sigma^\nu, \ (\alpha\beta^2)^\nu.$$

In the case of the elements antimony, bismuth, tin, zinc, cadmium, and silver, different principles of investigation have to be adopted, and their symbols are given according to two or more hypotheses.

The following table of the symbols of the units of certain well-known substances affords sufficient illustration of the method pursued:—

Symbol of	iodine	$\alpha\omega^2$
,, ,,	bromine	$\alpha\beta^2$
,, ,,	nitrogen	$\alpha\nu^2$
,, ,,	phosphorus	$\alpha^2\phi^4$
,, ,,	arsenic	$\alpha^2\rho^4$
,, ,,	chloric acid . . .	$\alpha\chi\xi^3$
,, ,,	ammonia	$\alpha^2\nu$
,, ,,	chloride of ammonium .	$\alpha^3\nu\chi$
,, ,,	phosphide of hydrogen .	$\alpha^2\phi$
,, ,,	oxychloride of phosphorus	$\alpha^2\phi\chi^3\xi$
,, ,,	acetylene	$\alpha\kappa^2$
,, ,,	alcohol	$\alpha^3\kappa^2\xi$
,, ,,	hydrocyanic acid . .	$\alpha\nu\kappa$
,, ,,	cyanogen	$\alpha\nu^2\kappa^2$

We quote the following from the concluding remarks of the author:—

"Our conclusions on this point are so remarkable, and so contrary to anticipation, that doubtless we could never trust them but for the simple and exact process by which they are deduced. Now, the conceptions which we form of the nature of the elemental bodies constitute the fundamental theory of the science, for these conceptions comprise and determine every similar conception. The unit of the element hydrogen is here conceived of as a simple weight, and symbolised by the letter α, That, to say the least, this view may be permitted, is proved by constructing the symbols of chemical substances upon this hypothesis. There are, however, certain exceptions, be they real or apparent, in which this mode of expression is impossible." . . "The unit of the element mercury, and the units of several other metals, such as zinc, cadmium, and tin, so far as our imperfect experience extends, appear to be analogous in this respect to hydrogen. But these are the only elements of this simple composition. The units of a second group of which the element oxygen, symbolised as ξ^2, may be taken as a type, and to which belong sulphur θ^2 and selenium λ^2, are composed of two identical simple weights, and the facts of the science do not permit us to assume these units as otherwise composed. Lastly, another group of elements appears in this system of a different and more complex composition, to which group belong the elements chlorine $\alpha\chi^2$, bromine $\alpha\beta^2$, iodine $\alpha\omega^2$, nitrogen $\alpha\nu^2$, phosphorus $(\alpha\phi^2)^2$, arsenic $(\alpha\rho^2)^2$, and, in all probability, numerous other elements. The simplest view which, consistently with the fundamental hypothesis, can be taken of the composition of these elements, regard being had to the total system of chemical combinations, is that they are severally composed of a unit of hydrogen and of two identical simple weights—as, for example, in the case of chlorine, of the simple weight α and two of the simple weights symbolised by χ, so that the elements of this group are to be considered as combinations of elements of the two previous forms respectively."

The author concludes by saying that from these and other equations "we unavoidably have suggested to us as the ultimate origin of our actual system of combinations . . . a group of elements, $\xi, \theta, \chi, \beta, \omega, \nu, \phi$ . . . of the densities indicated by these symbols, and which, . . . we cannot but surmise, may some day become, or may in the past have been, 'isolated and independent existences.' Examples of these simple monad forms of material being are preserved to us in such elements as hydrogen and mercury, which appear in the chemical system, as records suggestive of a state of things different from that which actually prevails, but which has passed away, and which we are unable to restore."

"Such a hypothesis is not precluded to us, but nevertheless we are not to imagine that it is a necessary inference from the facts. So far as the principles or conclusions of this method are concerned, the "simple weights" $\xi, \theta, \chi, \beta, \omega, \nu, \phi$. . . . may be treated purely as "ideal" existences created and called into being to satisfy the demands of the intellect, to enable us to reason and to think in reference to chemical phenomena, but destined to vanish from the scene when their purpose has been served; and the existence of which, as external realities, we neither assume nor deny."

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

Remarks on some Recent Contributions to the History of the Benzole Series, by* A. H. CHURCH, *M.A., Professor of Chemistry, Royal Agricultural College, Cirencester.*

THE more elaborate and exact study of the homologues and derivatives of benzole has revealed many most important facts. Admirable digests of these recent researches will be found in Will's *Jahresbericht* for 1865 (pp. 514 *et seq.*), and in the second volume of Kekulé's *Lehrbuch der organischen Chemie* (pp. 528 *et seq.*). My present object in writing on this subject is twofold—I wish to reassert my own discovery of several new substances and new reactions, and I wish to vindicate the accuracy of some of my experiments against the attacks which they have suffered from one or two foreign chemists.

Twelve years ago my first paper on the benzole series was published. Since that time not only have there

* Communicated by the author.

been made many additions to our knowledge of hydrocarbons and of the nature of isomerism, but the process of fractional distillation has also been materially improved. Thus it has come to pass that some of my former results I now interpret differently, some I have modified or further developed, some I have corrected in later papers, while some are discoveries now generally acknowledged, and which, in not a few cases, have served as starting-points for the subsequent researches of other chemists. I am compelled, therefore, to attribute, in some measure at least, the hostile criticism of Mr. C. M. Warren and Professor Beilstein to their imperfect acquaintance with the whole series of my published notes and papers. I do not wish to enter into any personal controversy with my critics, and I will not speak of the manner in which my reputation as a chemist has been assailed, but I do feel bound to restate the broad facts concerning the matters in dispute, drawing my data entirely from published sources.

These matters in dispute may be arranged under the three heads of—1. Boiling points; 2. The parabenzole series; 3. Reactions.

I. Boiling Points.—The boiling points I assigned† in 1855 to benzole and to the cumole from cuminic acid do not differ widely from those given by Mr. Warren,‡ and even the slight difference that exists is probably due to the methods adopted for correcting the observed temperatures—

	Warren.	Church.
Benzole . . .	80·1	80·8
Cumole . . .	151·1	148·4

With toluole, xylole, and cymole the case is different. Warren places the boiling point of toluole at 110·3°, my determination gave 103·7°,§ a result not far from that of Glénard and Boudault (106°) and that of Max Dürre. Coal naphtha, there is no doubt, contains a large quantity of a hydrocarbon boiling between 109° and 113°, and seemingly having the composition and properties of the toluole from toluic acid; but this fact is not incompatible with the co-existence of other hydrocarbons of the same formula. I may have placed the boiling point of toluole 6° too low; all I can say as to this matter is that the liquid boiling at 104° gave me every proof of its being toluole.

Xylole was discovered by Cahours in the light oils of wood naphtha. It was ascertained by its discoverer to boil between 128° and 130°. My experiments led me to fix its boiling point a little lower, at 126·2°‖; and as I obtained from coal naphtha an oil having the same composition and properties, and yielding apparently the same derivatives, I concluded the two hydrocarbons to be identical. Mr. Warren fails to discover in his sample of coal naphtha this hydrocarbon boiling at 126°—he concludes at once that it does not exist in any coal naphtha, and that my experiments are untrustworthy. As, however, Mr. Warren makes out Cahours to have been wrong as to his xylole, and tells us that Mansfield mistook cumole for cymole, I cannot think myself very badly off in sharing with those eminent chemists the censure of Mr. Warren, for, "if gold rust, what should iron do?" The liquid which Mr. Warren calls xylole is the petrole of Bussenius and Eisenstuck;¶ the pseudocumole¶ of W. De la Rue and H. Müller; my paraxylole,** and has also been redescribed by Béchamp†† and by Naquet.‡‡ But that the true xylole discovered by Cahours really does exist I cannot doubt. I would here merely add that the boiling point of my xylidine,§§ 213°—214°, differs by little more than 1° from the number assigned by Deumelandt‖‖ to xylidine obtained from a coal naphtha fraction boiling 13° above that which yielded my product.

The case of cymole still remains. Warren does not find this hydrocarbon in coal naphtha, while he affirms the boiling point of the cymole from oil of cumin to be 179·6°. Dr. Noad, who prepared large quantities of this liquid, gives 171·5° as its boiling point, while my determination was 170·7° for the oil as distilled from sodium, and 175° to 176° after treatment with oil of vitriol. This number 175° is that now generally confirmed by other chemists as the true boiling point of cymole.

The discrepancies between some of my boiling points and those more recently determined depend in great measure upon the different corrections applied to the thermometric indications, and also upon the existence in coal naphthas of two series of isomers, which seem to me to have been jumbled together by some observers. On this second point a word or two will at once explain my meaning.

Warren accepts 80·1° as the boiling point of benzole; the identity of benzole from various sources is generally allowed. Now cumole obtained from cuminic acid boils, according to Warren, at 151·1°. I do not suppose that any one has good grounds for controverting the statement that benzole from benzoic acid, and boiling at 80·1°, and cumole from cuminic acid, and boiling at 151·2°, are members of the same series. Both are derived by the same process from homologous acids.¶¶ If we compare, as we may fairly do, their boiling points, to what difference for C_2H_2 does it point? Not to Mr. Warren's 30°, but to the smaller difference of 23° or 24°.

Difference for $3CH_2$.

Benzole . . . 80·1° } 71·1° = 23·7° × 3.
Cumole . . . 151·2° }

Nearly all the difficulties suggested by the divergent results of different experimenters will be explicable if the existence in various coal naphthas of two or more series of benzolic homologues be granted. Warren, while readily admitting the occurrence of several similar isomeric series in different kinds of natural and artificial paraffin oils, seems to deny the occurrence of analogous variations in different samples of coal naphtha.

II. The Parabenzole Series.—In treating of the boiling points of the benzole series, I have necessarily referred to the existence of an isomeric series of hydrocarbons. Warren makes the very obvious suggestion that parabenzole is a mere mixture of benzole and toluole. I originally entertained the same notion myself till a close examination of the physical and chemical properties of this liquid convinced me that it was untenable. I have sufficiently combated this idea in my notes on the parabenzole series published in the volume of the Chemical News before cited.

The existence of an isomeric benzole has received strong confirmation in some experiments by Fittig, the occasional collaborateur of Beilstein. He finds a hydrocarbon, in some points closely resembling parabenzole, in

¶¶ The fusing points of the acids of the benzole series demand further investigation.

the products of the distillation of camphor with zinc chloride.

I will add one fact about the occurrence of parabenzole in coal naphtha which may serve to account for its non-detection by some observers. My experiments were made with fractions boiling at about 100°, and which had been collected during some years in numerous distillations of large quantities of the naphtha; yet a few ounces only of parabenzole was the ultimate product.

III. Reactions, and New Compounds and Processes.—The following are the chief points under this head to which I would wish to call attention. I claim as my own the following processes, methods, &c., most of which have been republished of late years as new discoveries or adopted without acknowledgment:—

1. The purification of hydrocarbons by distillation from sodium. (*Phil. Mag.* 1855.)

2. The production of the so-called "nitro-sulpho" acids by dissolving nitrobenzole, &c., in oil of vitriol or Nordhäusen acid. (*Ibid.* 1855.)

3. The oxidation, by chromic acid, of nitrotoluole and its homologues into β nitrobenzoic acid, &c. (*Ibid.* 1861.) In 1862 I showed in the International Exhibition a specimen of this β nitrobenzoic acid thus labelled and distinguished from the ordinary α acid.

4. The oxidation of sulpho-toluenylic acid into benzoic acid by the action of chromic acid.

5. The probability of the existence of methyl-benzole, &c. (*Phil. Mag.* 1859.)***

I trust that none of the foregoing remarks will lead any one to suppose that I underrate Mr. Warren's own researches. While demurring to much of his criticism, I look upon some parts of his experimental investigation as monuments of patient labour and as most valuable additions to our accurate knowledge of a complex subject. And, with reference to Professor Beilstein, I am far from denying that in some particulars his criticism, though rough, is just. For example, in my earlier papers I rested my convictions of the identity of some of the benzolic homologues from various sources upon experimental grounds, which have since been shown to be inadequate. Then, again, I stated in 1855 (*loc. cit.*) that coal-tar toluole, by digestion with sodium, yields two hydrocarbons differing in boiling point—an assertion which is erroneous if pure toluole be operated upon, but which I myself corrected in 1857, explaining, at the same time, the real facts of the case. In the other charges which Professor Beilstein brings against my statements, I believe him to be unjust, and that he is so in some instances may be proved very readily. He states††† that I assert xylole to be changed into benzoic acid by oxidation with chromic acid. The fact is that, on the contrary, I offered no experiments of my own on the subject, but simply stated‡‡‡—"I have *not* yet experimented with the *xylole* series!" The last matter in which my reputation is assailed is as to the identity of the α and β nitrobenzoic (nitrobenzoic and nitrodracylic) acids; as already stated, I affirmed them to be different as early as 1862. But Professor Beilstein is not content with charging me with the terrible mistake of confounding two bodies which every one knows are actually *isomeric*, for he does me the further kindness of recommending *my* process as the best method of preparing the β nitrobenzoic acid! He does this without acknowledgment in his attack on another chemist.§§§

PHYSICAL SCIENCE.

*On the Occlusion of Hydrogen Gas by Meteoric Iron,** by THOMAS GRAHAM, *F.R.S.*

SOME light may possibly be thrown upon the history of such metals found in nature as are of a soft colloid description, particularly native iron, platinum, and gold, by an investigation of the gases which they hold occluded, such gases being borrowed from the atmosphere in which the metallic masses last found themselves in a state of ignition. The meteoric iron of Lenarto appeared to be well adapted for a trial. This well-known iron is free from any stony admixture, and is remarkably pure and malleable. It was found by Wehrle to be of specific gravity 7·79, and to consist of—

Iron	90·883
Nickel	8·450
Cobalt	0·665
Copper	0·002

From a larger mass a strip of the Lenarto iron 50 millimetres by 13 and 10 millimetres, was cut by a clean chisel. It weighed 45·2 grammes, and had the bulk of 5·78 cubic centimetres. The strip was well washed by hot solution of potassa, and then repeatedly by hot distilled water, and dried. Such treatment of iron, it had been previously found, conduces in no way to the evolution of hydrogen gas when the metal is subsequently heated. The Lenarto iron was enclosed in a new porcelain tube, and the latter being attached to a Sprengel aspirator, a good vacuum was obtained in the cold. The tube, being placed in a trough combustion furnace, was heated to redness by ignited charcoal. Gas came off rather freely, namely—

In 35 minutes . .	5·38	cub. centims.
In 100 minutes . .	9·52	,,
In 20 minutes . .	1·63	,,
In 2 hours 35 minutes	16·53	,,

The first portion of gas collected had a slight odour, but much less than that of the natural gases occluded from a fire by ordinary malleable iron. The gas burned like hydrogen. It did not contain a trace of carbonic acid, nor any hydrocarbon vapour absorbable by sulphuric acid. The second portion of gas collected, consisting of 9·52 cub. centims., gave by analysis—

Hydrogen . .	8·26	cub. centims.	85·68
Carbonic oxide .	0·43	,,	4·46
Nitrogen . .	0·95	,,	9·86
	9·64		100·00

The Lenarto iron appears, therefore, to yield 2·85 times its volume of gas, of which 86 per cent. nearly is hydrogen. The proportion of carbonic oxide is so low as 4½ per cent.

The gas occluded by iron, from a carbonaceous fire, is very different, the prevailing gas then being carbonic oxide. For comparison a quantity of clean horse-shoe nails was submitted to a similar distillation. The gas collected from 23·5 grammes of metal 3·01 cub. centims.) was—

In 150 minutes . .	5·40	cub. centims.
In 120 minutes . .	2·58	,,
In 4 hours 30 minutes .	7·98	,,

The metal has given 2·66 times its volume of gas. The first portion collected appeared to contain of hydro-

* Read before the Royal Society, May 16, 1867.

gen 35 per cent., of carbonic oxide 50·3, of carbonic acid 7·7, and of nitrogen 7 per cent. The latter portion collected gave more carbonic oxide (58 per cent.) with less hydrogen (21 per cent.), no carbonic acid, the remainder nitrogen. The predominance of carbonic oxide in its occluded gases appears to attest the telluric origin of iron.

Hydrogen has been recognised in the spectrum analysis of the light of the fixed stars, by Messrs. Huggins and Miller. The same gas constitutes, according to the wide researches of Father Secchi, the principal element of a numerous class of stars, of which α Lyræ is the type. The iron of Lenarto has no doubt come from such an atmosphere, in which hydrogen greatly prevailed. This meteorite may be looked upon as holding imprisoned within it, and bearing to us, hydrogen of the stars.

It has been found difficult, on trial, to impregnate malleable iron with more than an equal volume of hydrogen, under the pressure of our atmosphere. Now, the meteoric iron gave up about three times that amount, without being fully exhausted. The inference is that the meteorite has been extruded from a dense atmosphere of hydrogen gas, for which we must look beyond the light cometary matter floating about within the limits of the solar system.

FOREIGN SCIENCE.

(From our own Correspondent.)

Paris, May 28, 1867.

At the meeting of the Society of Encouragement on May 17, M. Tresca, who replaces M. Combe in the secretary's chair, paid a high compliment to the new steam engines of M. Duvergier, the constructor of the boats now plying on the Saone and Loire; he pointed out improvements in the machinery and in the employment of steam.

M. Julien Caûdron, ropemaker at Malaunay (Seine Inférieure), submitted to the Society (Rope Section) ropes, splices, and knots of cotton, which, owing to their tested strength and cheapness, are preferred, for naval purposes, in some cases to hemp ropes. Experiments made at the several seaports amply confirm the hopes of the inventor.

M. Payen resumed, in a rather long but learned and interesting discourse, the progress accomplished in the fabrication of paper, parchment, and the employment of parchment paper for the separation, by endosmose, of the salts which hinder the extraction and crystallisation of sugar contained in juices, syrups, and molasses. After having called to mind the physical and chemical composition of herbaceous or woody fibres, he enumerated—1. The papers of MM. Bachet and Machard, who treat the sprigs of fir first by hydrochloric acid, and afterwards by chloride of lime to bleach them. 2. The papers made from seaweed and other marine plants obtained nearly in the same manner by MM. Poinsot, Breton, &c. 3. The lucern papers of M. Caminade, the wild-thistle papers, the straw and sparta papers, &c. 4. Chinese rice papers, or those made from the pith of the *Laruca paperia*; 5. The parchment papers of M. Neumann, at St. Denis. We shall not return to the subject of the osmose of sugars, as we think our readers are already sufficiently initiated into it.

M. Isambart had at work two magnesium lamps, the first being exactly similar to that of M. Solomon. A movement by clockwork rapidly unrolls the magnesium wire, which is coiled on a bobbin. It has the inconvenience of disengaging too much white vapours of magnesia, which for a moment obscure the light. The second is only a modified Larkin's lamp; and M. Isambart should not have omitted to mention his name. An ordinary spirit-lamp occupies the bottom; a glass tube forms a chimney; a small box or recipient containing magnesium in powder mixed with 50 or 80 per cent. of fine sand. By turning a small button a cock is opened; the mixture is inflamed, and burns with a very brilliant light. We prefer the first light to the second, of which the intermittent and unsteady light is intolerable to the eye. M. Isambart said that the expense per hour of the second lamp was about 3 fr., and that the price of magnesium may still be lowered. At 3 fr. this intense light is not too dear.

M. Durand presented, and set at work, a small model of a brick-making machine, representing one of the novelties of the Exhibition, of which we shall speak shortly.

M. Julien presented a pamphlet on iron and steel. We do not wish to enter into controversy here on this subject, only we notice that iron and carbon do not combine; they only mix together as water and oil.

M. Emile Petit sent specimens of artificial lithographic stones. We wish him success, as the lithographic presses of MM. Kocher and Houstiaux require for continuous impression cylindrical stones of a size difficult to be found in nature.

M. Lavollée, in the name of the Committee of Commerce, read a report on the exportation of the habitable constructions by M. Benis. Two portable private houses were sent out to the Island of St. Thomas. The walls were formed of two vertical and parallel sheets of scagliola or imitation of marble, the interior being filled up with wood shavings, alga marina, &c. The ceilings are partly of iron and partly of wood subjected to the process of injection of sulphate of copper and tar afterwards. The floors are of imitation marble, &c. The cost of the two houses was 45,000 fr., including 1100 fr. for the carriage. Their aspect is exactly that of houses built of marble.

M. Tresca made a communication on the mechanical applications in the interior of mines. Works in mines require a motive power, either sudden and discontinued or continuous and slow. In the first case, the best motor is compressed air; in the second, water under pressure. As in tunnel work there can be no admission of fire, combustion, or the engendering of steam. Compressed air has been happily employed by M. Sommelier for the engines used by him in the tunnel of the Alps. Water under pressure was employed by M. Perret in the works of the South of France railways, to give a rotatory movement to the rings or circles of M. Deschaux, armed with diamond points for cutting the hardest rocks. The great problem of the day is the mechanical getting of coal. He explained and put before the eyes of the members two models; one of Carrett, Marshall, and Co.'s coal-cutting machine, the other of that of Jones, Levick, and Co., of Newport, Mon.

PARIS EXHIBITION OF 1867.

(From our Special Correspondent.)

Group V.—Class 44: *Chemical and Pharmaceutical Products.*

Felix Dehaynin, of Paris, has founded at Aubervilliers, near Paris, some large chemical works, for the treatment, on a large scale, of the products of the distillation of coal tar. One would scarcely believe that the quantity of coal tar annually distilled in the manufactory of Gosselies, where the dust and small coal are agglomerated in the form of small bricks, of immense utility for railway locomotives, amounts to eight or ten thousand tons. It is then treated by another operation, and transformed into benzol, nitrobenzol, and aniline, substances employed for the preparation of the new colours, the solution of caoutchouc, removal of grease from stuffs, leather varnishing, &c. The benzol, nitrobenzol, and the aniline of Aubervilliers are much esteemed. The eye cannot con-

template without astonishment the array of twenty-five bottles, which only form a part of the products of the distillation of coal.

The glass case of M. Robinet, of Paris, 3, Rue de l'Abbaye Saint-Germain, formerly President of the Academy of Medicine, is distinguished from his neighbours' by the fact that he sells nothing, that he gives away all the products he obtains—that is to say, his numerous analyses of waters—and he limits himself to the task of soliciting new ones, which he analyses in succession, and gives gratuitously the results of his analyses to those who send the samples. He even goes so far as to give bottles of certain waters to those who, for particular reasons, would be interested in knowing the nature of those in their neighbourhood; and he bears the expense of carriage, bottles, &c., even if they are sent to the other end of the world. What motive has induced M. Robinet to make so many great sacrifices, and to give himself so much labour? Nothing is more simple to answer. He has undertaken to fill up a void in the physical history of our country; he has given to science, industry, agriculture, and public salubrity, a Hydrographic Dictionary of France. There exist, undoubtedly, already, numerous documents from which such a work might be compiled; but they are scattered about and incomplete. The "Geographical Dictionary" no longer exists. The work of 221 pages, published under this title in 1787, by M. Mothey, geographer to the king, did not fulfil the required result. M. Robinet set courageously to this task after the work he had performed as reporter to the commission of inquiry for the diversion of the waters of the Dhuys. He proposes to treat of soft or potable waters in a statistical, geographical, geological, chemical, economical, hygienic, and agricultural point of view. A first essay, already published, devoted to the study of the basin of the Marne, amply proves that the author will complete his programme.

In his glass case we find a hundred specimens of water, and one of the labels bears the number 2082. In fact, M. Robinet has analysed more than 2000 waters! His exhibition is only intended to invite remittances of water from the four quarters of the globe. We would say that his appeal has already been responded to, for we find in the galleries waters from London, the Danube, &c., and there is every reason to hope that the geographical dictionary especially devoted to France will also interest, in a greater or less degree, most of the foreign nations. We sincerely wish that, among the numerous pilgrims to this great *fete* of nations, some will not object to encourage his work and send specimens of waters. The notation for the representation of watercourses of M. Robinet is well worthy the attention of hydrographic and other engineers, his new system gives immediately a very exact idea of the direction, extent, inclination, and other essential characters of watercourses. In order that the remittance of water to be examined may be complete, it should comprise the waters of the rivers, brooks, and wells, with the nature of the soil in which they rise, drainage water, rain water collected in an earthenware or porcelain vessel, and drinking water from the public fountains.

We find in the glass case of M. Joly, of La Rochelle and Paris, No. 13, Rue d'Antin, a very original and new product—viz., marine silk. M. Joly discovered in the eggs of fishes of the family of Sebacians (the ray) that their exterior envelope is formed of a very close tissue, composed of an infinite number of delicate filaments which are easily removed and separated. Once drawn out they possess the appearance, colour, and finish of cocoon silk, serving without trouble for tissues of ordinary silk or silk wad. The interior of the eggs contains an albuminous white substance which can serve usefully in competition with the white of hens' eggs for printing on tissues; they contain a considerable quantity, as each roe weighs on an average 240 grammes (about ½lb.) The manufacturing industry of tissues will certainly make good use of these new products.

We also remark in the collection of M. Joly:—1. His cream of cod-liver oil, much more agreeable to the taste, and more digestible, than the best and purest ordinary cod-liver oil. 2. His qualus-liver oil, which M. Joly was the first to think of extracting from these fishes. 3. Fish-liver oil for leather manufacture. 4. French guano, a manure formed of edible fish and the debris of fisheries, very much sought after by agriculturists, and which is likely to improve the condition of the fishermen, as they can sell with profit what was formerly thrown into the sea.

The pharmaceutical establishment of M. Ch. Genevoix, 48, Rue Bonaparte, was the first that, thirty years ago, manufactured in quantities of a ton a day, ferruginous pills and lozenges. His syrups of iodide of iron and his purgative lemonade are remarkable for their indefinite preservation. His gaseous powder replaces, weight for weight and with much economy, tartaric acid in the preparation of aerated waters in the gazogene apparatus with two compartments. The Paris hospitals employ every year, on an average, 10,000 packets. The quality, the attractive form, the low price, and excellence of manufacture combine to render the establishment of M. Ch. Genevoix a model pharmacy.

M. Emile Genevoix, 14, Rue des Beaux Arts, exhibits feculous seeds and fruits containing from 1 to 10 per cent. of different oils which play an important part in alimentation. Disseminated between the grains of starch, these oils can be extracted by means of sulphuret of carbon, chloroform, benzol, ether, &c. M. Genevoix substituted for these solvents, firstly, carbonisation by sulphuric acid, which, in spite of the high temperature produced, set the fatty matters at liberty, without destroying them, in a state easily soluble in menstrua, or able to be obtained in a greater quantity by distillation. But this method was too costly when it was used on the large scale, and it has given place in the factory of M. Genevoix to an industrial process which allows the production by tons weight of the oil of some fruits, very abundant and without value—the horse-chestnut, for example. Bought at 40 or 50 fr. the ton, the finest chestnuts are rasped, submitted to a full fermentation, boiled in ten times their weight of water, and transformed into glucose by the addition of 2 per cent. of sulphuric acid. The liquor, freed from insoluble portions, is submitted to a slow ebullition, which allows the oil to agglomerate at the surface particle by particle. Drawn off and filtered, this oil is sold to the public without any addition. For ten years past the average quantity of oil manufactured in the chemical works at Romainville has been 600 kilogrammes, extracted from fifty or sixty tons of horse-chestnuts, which were bought from agriculturists for 2500 to 3000 fr. The wholesale price of the oil is 20 fr. Vegetable wax is separated from it under the form of stearin, margarin, &c. The water on which the oil floats, when neutralised, gives "syrup of glucose," and "horse-chestnut alcohol," prepared for trade on a large scale. The fabrication of starch had to be abandoned, as the supply of horse-chestnuts was uncertain and insufficient.

This fatty substance, very fluid, absorbable by the skin, has a place marked out in the therapeutics of the gout and rheumatism—in fact, the chestnut oil of M. Genevoix has been found very efficacious, and enjoys a great success.

M. Genevoix, struck with the happy effects obtained by the valerianate of ammonia, has combined valerianic acid with other new base. His valerianate of triamyline contains four equivalents of valerianic acid. If the medicinal action depends upon the acid, and not upon the base, the new compound cannot fail to be successful.

Poultices are attended with great inconvenience in consequence of their weight, their cooling, and their more or less disagreeable odour. For the application on the skin of liquid medicaments, laudanum, tincture of iodine, or fatty matters, M. Genevoix proposes an impermeable

tissue enclosing a double layer of swanskin, which is wetted with a decoction of marshmallows, linseed, or poppyheads, and which preserves its temperature for more than twelve hours at 70° C.

A Course of Four Lectures on Spectrum Analysis with its Applications to Astronomy, by* William Allen Miller, *M.D., LL.D., Treasurer and V.P.R.S., Professor of Chemistry, King's College, London.*

Lecture II.

Spectra of Simple Bodies.—Spectra of Compounds.—Effect of Temperature upon each of these Classes of Spectra.—Mode of Comparing Spectra with each other.—Analysis of Artificial Flames by the Spectrum.—Nature of Information thus obtained.—Discovery of New Metals by the Spectrum.

In the last lecture I brought before you three different classes of spectra—1. The spectra produced by the ignition of solid and liquid bodies, which are continuous. 2. The spectra of ignited gases, which are discontinuous or interrupted. 3. Composite spectra, the result of the action of the spectrum of an ignited gas or vapour upon a continuous spectrum at a higher temperature which is transmitted through the gaseous spectrum. We have, therefore, 1, spectra exhibiting one continuous shaded band of varying colour, from red, on the one hand, to violet on the other; 2, spectra in which certain colours only are present, each band of colour being perfectly definite and referable to the particular substance by which it is produced; and 3, we have absorption spectra produced by the superposition of this second class of spectra upon the first.

I purpose to-day to confine our attention chiefly to those spectra which are furnished by the incandescence of gaseous matter under different conditions—different specially as regards temperature; for the study of differences of this kind is particularly necessary to enable us correctly to interpret the changes going on in objects at a distance.

It is a remarkable, but, at the same time, not, perhaps, on consideration, a very surprising fact, that the same substance in the liquid or solid condition should give out a very different spectrum from that which it exhibits in the gaseous state. The particles of which bodies consist in the solid or liquid form are fettered, so to speak, by association with each other. Consequently, the vibrations to which they give rise are, of necessity, of a more composite order than those which would be produced by the same substance if it were converted into the gaseous condition, where its particles not only have no mutual attraction, but are powerfully self-repulsive. These ultimate particles or atoms, in the case of simple bodies—molecules in the case of compound bodies—by the fact of their being raised in temperature, acquire motions of their own, which they are able to communicate to the ether; and by these motions they occasion in us the sensation of light
